THE MIRACLES AT THE TOMB OF B. FRANÇOIS DE PÀRIS.*

By JOSEPH COLLINS, M.D.

NEW YORK.

To gain a satisfactory idea of the conditions that lead up to the miracles of which I shall speak it is necessary to know something of the conflict that existed at the time of their occurrence, in France, and to a lesser extent throughout other parts of Europe, between Jesuitism and Jansenism. The history of the former, still the most vigorous and aggressive institution within the Catholic Church, is well known. The cause of the Jansenists was buried in the grave of François de Pàris nearly two centuries ago. Practically the only evidences of its survival is the existence of such persons as Augustin de Chanteprie in Marcelle Tinayre's remarkable novel "Maison du Peche" and a few disciples of St. Augustine, the first great father of the Latin Church.

*Read at a meeting of the Charaka Club, February, 1908.

In 1640 Cornelius Jansen published his celebrated work on the teachings of the Sainted Bishop of Hippo. It had a great and an immediate success. In it the errors of the Jesuits were pilloried with the Massilians and followers of the British monk, Pelagius, whose doctrines had been refuted by St. Augustine twelve centuries before. The Jesuits parried the thrust by means of the bull of Urban VIII, which forbade the reading of the "Augustinus." The best advertisement for a book then, as it is now, was to say that it was not fit to read. It had a wide circulation, so they had its doctrines pronounced heretical by Innocent X in 1653. It was then that the famous Port Royalists, Antoine Arnauld, the theologian, who had been expelled from the Sorbonne, and Blaise Pascal, the philosopher, scientist, and litterateur, and others less known to posterity tried unsuccessfully to stem the tide was sweeping away Jansenism.

The controversy gave birth to a classic of literature, "Pascal's Letters to a Provincial by One of His Friends," which was, as Pater terms it, nothing less than a revelation to all the world of the capabilities, the true genius of the French language in prose. The Provincial letters had immediate suc-

FIG. 1.—The Tomb of B. François de Pàris. "Made illustrious by miracles without number and by startling conversions."

cess. "All the world sees them; all the world understands them." For a time they seemed to controvert the doctrine of "sufficient grace," in which the Jesuits had presented a view of the conflict of good and evil in the soul, but it was only a temporary victory. Pascal soon succumbed to a hopeless and inexplicable malady at the age of 39, the age fancifully noted as fatal to genius, and with him went the most valorous champion of the cause. The Jesuits were again in control. They did not take their security for granted, however. The Argus of the society was ever at his post in those days, and a generation later, when Quesnel's popular book "Moral Reflections on the New Testament," which was suspected of latent Jansenism, was published, they got the bull, "Imigenitus" (1713), from Clement XI, condemning its teachings as erroneous and heretical. This bull divided the French Church into two parties, the Acceptants and the Appellants. The Jansenists and their sympathizers were all in the latter camp, and as it included the cardinal archbishop of Paris it constituted a formidable party. Then the Jesuits played their winning card. They had the bull "Imigenitus" registered as a law of the kingdom and Jansenism was a matter of history, but before giving up the ghost it gave one universal shriek, louder than the loud ocean, like a crash of echoing thunder: the miracles wrought upon the grave of a young Appellant deacon, François de Pâris. The Jesuits could defeat men but not God. If miracles were performed at the grave of dead Appellants through the mediation of the holy spirit of the sacred interred, no argument was needed to convince that they were the elect. Miracles had been somewhat in their line before as testifies the cure, otherwise inexplicable, wrought in May, 1656, upon little Marguerite Périer, niece of the famous Pascal. A fragment of the crown of Christ, preserved at the celebrated Cistercian Abbey, Port Royal, cured her of a lacrymal fistula which had resisted all known treatment. The Jesuits were much mortified at this miracle, which, as it was officially recognized, they could not deny. But it was not until after 1730 that the occurrence of miracles menaced the Jesuits' existence as the controlling power within the Church. For nearly twenty years the grave of the sacred Deacon de Pâris was the Mecca of the lame, the halt, and the blind. Thousands visited it daily. The State and the Church both tried to suppress the enthusiasm of the throngs that visited the grave each day.

Fig. 2.—Dom Alphonse de Palacios; ill.

Fig. 3.—Dom Alphonse de Palacios, recovered.

Many of them were thrown into prison, the place was walled up, Acceptants thundered against it, but all to no purpose.

The records of some of the cures that were wrought at this grave are contained in three large volumes entitled "La Vérite des Miracles Opérés a l'intercession de M. de Pâris et Autre Appelans démontrée contre M. l'Archevêque de Sens" (Languet), published in Paris 1737-1741. Some of the more striking illustrations contained in these volumes are here reproduced.

The author of this remarkable work, Carre de Mongeron, was born in Paris in 1686. He was an only child, and, judging from his own statement, his young life was very licentious. In reality he was a petted and indulged youth. He went through the customary phases of puberty, including the religious phase, when he convinced himself that he was a pillar of atheistic strength. A fright, induced by the running away of a pair of horses which he was using to aid him in abducting a girl, led him to go into a monastery that he might there atone for his sins, but as soon as the effects of this jar to his courage and to his vanity wore off he found that he was still a bad man. He returned to Paris and there continued to live the life of a libertine, meanwhile trying to win his father to his irreligious views.

In 1731, viz., in his forty-fifth year, he first heard of the miracles performed at the tomb of M. L'Abbé de Pâris. At first he attempted to ignore them, his attitude toward such things being wholly sceptical, but it finally occurred to him that if miracles were worked by the dead body of a Roman Catholic there must be something in that faith which he did not appreciate. He decided to put by his convictions of scepticalness and to visit the tomb and see for himself. Overwhelmed with religious ardor, chastened by the thought of the possibility of

Christ's miracles and the result of them, he experienced an inward illumination while kneeling at the tomb of the sacred deacon which gave him at the same time a benign humility and a majestic exaltation. Like the poet, he thought:

"Could I find a place to be alone with Heaven
I would speak out: 'Heaven is my need;
Every woodland tree is flashing like the dogwood,
Flashing like the white beam, swaying like the reed."

He must tell someone of this wonderful transformation that has gone on within him, and he seeks his religious instructor, who tells him that such sudden illumination must be a miracle, which M. de Mongeron is only too glad to believe. From this time henceforth he devotes himself to a study of the miracles that had been and were being performed at this tomb and at the tombs of other sacred Appellants and to defending the verity of them against the Archbishop of Sens, who made it his business to attempt to ridicule and deny them.

De Mongeron's work is a monument to his piety, an earnest of his faith, and a permanent testimonial to his industry. Apparently he did not believe that God would hedge in the way to one to whom light was given. For us it has a peculiar interest, insomuch as it contains the most graphic accounts of major hysteria that have ever been depicted by the hand of a layman. The illustrations that accompany them are no less remarkable than the text, and they compare favorably with the illustrations from the Salpêtrière that set forth the manifestations of this majestic psychosis. Taken all together, they depict practically every form of physical incapacity and disorder which are now called the stigmata of the disease.

The frontispiece of Volume I is a picture of François de Pâris kneeling in his room before an image of Christ. The facial expression and the attitude of his body indicate an abandonment to the will of the Lord and a willingness to accept any message which may come from Him. This celebrated penitent, son and brother of counsellors of Parliament, had carried the cross of the Sufferer from his tenderest youth, and even in infancy had given indications of singular piety, with a taste for mortification of the flesh which has rarely been surpassed. All these virtues, says M. de Mongeron, were augmented during the course of his life. Prayers, study, and retreat were the deliciousness of his soul, and to the indulgence of them he gave himself wholly. Although he is said to have loved his parents, it became him better to live in the mansion of his Saviour, and, like St. Francis of Assisi, for the accomplishment of this he distributed to the poor all his worldly possessions and devoted himself to the Lord. To this state of humiliation he added penance and austerity, prostrating himself at the foot of the cross, and he despised not the chastening of the Almighty!

He mutilated his body by instruments of penitence in order to obtain the clemency of God, and, that light from Him might penetrate his soul. According to our author, his soul soon became flooded with light from above and treasures of the Almighty expanded within him in profusion. The heavens opened and there descended upon him a wealth of marvels which still last. Light was given to him that was in misery, and life unto the bitter in soul. Death, which has obliterated the recollection of most of the great people of his century, only made him celebrated throughout the entire world—this illustrious penitent, obscure and unknown during life. Scarcely had his soul separated from his body than a great number of persons were inspired to bespeak his intercession with the Lord in order that their infirmities might be overcome. His illustrious tomb became the sanctuary of most striking miracles, the great and the rich vied with the poor and those of no distinction save profound humiliation to lay themselves upon it in order that they might get miraculous aid. Theists and atheists, astonished by the new light which presented itself to their souls, prostrated themselves humbly in the dust and made public the abjuration of their incurability.

Fig. 4.—La Demoiselle Thibaut; ill.

Fig. 5.—La Demoiselle Thibaut; recovered.

The second illustration in Volume I represents the tomb of the sacred Deacon (see Fig. 1). It bears the legend from Isaiah, "Say to them that

are of a fearful heart, Be strong, fear not; behold your God will come with vengeance, even God with a recompense. He will come and save you. Then the eyes of the blind shall be opened, and the ears of the deaf shall be unstopped."

The next illustration (Fig. 2) represents Dom

Fig. 6.—Marie Anne Couronneau ill.

Alphonse de Palacios, a young Spanish grandee, who, suffering from an inflammation of the right retina to such an extent that he could not tolerate the slightest light, was taken, on the 30th of June, 1731, to M. Gendron, a celebrated surgeon of Auteuil, who pronounced the disease incurable or, at least, one that could be benefited only by very protracted treatment. This young man's history is interesting: Six years before, *i.e.* in 1725, he had an inflammatory condition of the left eye which destroyed its function. He lived in constant fear that something might happen to the other eye, and that he would become blind. Despite his precautions he received a blow on the right eye and he became blind for eight days. This terrorized him profoundly, although the right eye recovered. But, says our author, "The left eye having been entirely destroyed, and as the optic nerve which goes to this eye is joined to the optic nerve which goes to the right eye, it gradually communicated its destructive process to it. Dom Alphonse, reduced to a state of most profound despair, particularly after the unsatisfactory consultation with his physicians, begged to be allowed to go to the tomb of the Diacre de Pâris, but many obstacles were put in his way, particularly by the Church. Nevertheless, he finally accomplished his purpose and made a nine-day devotion at the tomb at St. Menard, but it availed him not. His eye got worse. Then it occurred to him that if he bound up his eye with a part of the shirt in which the sacred penitent had died he would get well. Almost immediately after the application he got relief. Then he bound it up a second time, and when he awakened from the sleep which came over him he appreciated that he was cured. He went at once to the tomb, and there he gave himself up to overwhelming feelings of gratitude and to transports of ecstasy and then his recovery was complete (Fig. 3). Two days later, like a considerate patient, he went to see M. Gendron so that he might bear witness to his recovery. M. Gendron, who was in his garden, seeing him from afar walking without anyone to guide him, his eyes without bandage and wide open, apparently reveling in the rays of the sun, was so astonished that he

Fig. 7.—Marie Anne Couronneau; recovered.

scarcely gave credence to his own vision, but he ran to meet him crying, "What have you done, Monsieur, your eye seems to be in good shape?" Dom Alphonse told him the story and related his experience. M. Gendron examined the eye with the most exact attention and declared that the interior was as perfect as the exterior, and that he was entirely cured. He also modestly added that M. de Paris, dead, had done in a night what he or the most talented surgeon of the world could not do in three months, all of which shows that M. Gendron not only had the humility that is characteristic of his cult, but that he was a sly old fox as well, for at the previous interview he had pronounced the disorder hopeless. He also added that the cure was a miracle, no doubt about that, from which the inference is legitimate that M. Gendron was almost up to miracles himself.

This is really a most interesting case; an impressionable boy had had his left eye put forever out of commission, then he worried constantly lest he should lose the other. He got a slight blow on the other and total transitory amblyopia was the result. This passed away and then gradually there developed what was probably a concentric limitation of the visual field until the sight became practically obliterated, and with this was associated photophobia and other manifestations of hysterical blindness. The illustrations depict the bandaged youth led by an able-bodied young man to M. Gendron, who is being implored by both of them and by another to do something for his relief. The second illustration depicts Dom Alphonse entirely restored at the tomb of Diacre de Pâris with outstretched hands and uplifted head, gazing into the heavens, where the sun is shining brilliantly. His companions, who had led him to the surgeon, knelt behind him and joined with him in giving expression to their gratitude for this miraculous cure.

The Archbishop of Sens made a remarkably acute observation concerning this case: "Never," said he, "was a miracle so ridiculously imagined. If God wished to make a miracle, why would He cure one eye and not the other?" The writer of the book, however, says we have no right to inquire into the motives that prompt the Lord to make such discrimination. Upward of a hundred pages of closely printed matter are taken up with a description of the case, demonstration of the cure, testimonials of innumerable people who knew the boy before and after, and all the other paraphernalia that tend to lend verity.

The second cure was even more striking than the first. Miss Thibaut, 05 years old, had been afflicted since her sixtieth year with a universal dropsy which reduced her to such a state of feebleness that she was unable to move. "Her legs were as large as the body of a child, her feet round as her head, the left side in a state of complete paralysis and contracture, the fingers of the left hand ankylosed and covered with ulcers" (Fig. 4). The patient, in this state, was brought to and placed upon the tomb of M. de Pâris on the 19th of June, 1731, and wrapped in a sheet which it was thought would be her shroud. On the tomb itself were placed her slippers, of the most approved Cinderella pattern, and with exaggerated Louis XV heels! She was cured almost immediately. The dropsy melted from her swollen members, in full view of the spectators, like the mist before the morning sun. She got up and, sitting on the side of the tomb, joined her hands in prayer, thus demonstrating that the left hand, which had been paralyzed, and the fingers, which had been covered with ulcers, were cured. Her servants put the exquisite objects of art called slippers upon her feet, while she and the others about her gave vent to their astonishment and wonderment, each in his own way (Fig. 5).

Fig. 8.—Marguerite François du Chêne; ill.

Hysterical edema, paralysis, and contracture are common stigmata of major hysteria, and Mlle. Thibaut's case presents no difficulties of interpretation, particularly when we learn that her illness began with a profound "apoplexy," from which she recovered only to develop vomiting, swelling of the abdomen and of other portions of the body, and finally new attacks of "apoplexy," followed by extraordinary trembling in all the extremities, and later rigidity of the left upper extremity. The attacks of apoplexy were the ordinary syncopal manifestations of major hysteria, while the peculiar deformity of the fingers of the paralyzed hand occurs only in hysteria, not in organic hemiplegia.

The third miracle was that of Marie Anne Couronneau, an old women of 68 years, completely paralyzed on the left side. She went to St. Menard on the 13th day of June, 1731. She could walk only on two crutches, and she had a harness as well suspended from her neck. At each step she was obliged to support herself not only on the crutches, but to throw herself backward, making most violent efforts in order to draw her left leg forward (Fig. 6). Two surgeons decided that the paralysis of her left leg was complete and absolutely incurable, but she was suddenly and perfectly cured on the day she went to the tomb. The second picture (Fig. 7) shows her mounting the stairs with an alacrity that would befit a maiden of fifteen, the crutches waving aloof—one in either hand—the harness falling useless at her side, and a sort of a battle-cry-of-freedom expression upon her face.

The fourth case was that of Marguerite François du Chêne, who for three years had most frightful hematemesis, caused by the rupture of several blood-vessels in her stomach. For five years she had been consumed by a continuous fever and tormented by a pain in the side, which caused constant insomnia. To add to her misery her entire left side was paralyzed and her entire body was pervaded with the dropsy (Fig. 8). Several attacks of apoplexy and of lethargy had reduced her to such a state that she was considered to be *in extremis*.

Fig. 9.—Marguerite François du Chêne; recovered.

Within three days she was entirely cured at the tomb of the sainted Deacon. Her figure so far resumed its serpentine form that she was obliged to fold her mantle around her to give it anything approximating a fit (Fig. 9).

This is one of the most striking of the cures, hysterical hematemesis, paralysis, convulsions, and edema being the most common stigmata of major hysteria. The detailed description which M. de Mongeron gives of the various symptoms and the way in which they displayed themselves at various

Fig. 10.—Philippe Sergent; ill.

times reminds one of a typical case from the Salpêtrière. We can readily imagine the stage of desperation she reached when physician after physician failed to give her relief. The description of the way in which cure came to her is no less graphic than that which depicts her symptoms, while the documentary attestations of her cure would put any modern Thomas to shame.

The fifth miracle is one of the most brilliant of them all. Philippe Sergent, whose left side was paralyzed, the knee being firmly ankylosed and the muscles of the lower extremities atrophied (Fig. 10), was instantly and completely cured on being conducted to the tomb on the 10th of July. He flung down his crutch and cane, mounted the tomb, and sang lustily a *Te Deum* (Fig. 11).

The sufferings of M. Sergent were not to be compared with those of Pierre Gautier de Pezenas, the victim of the sixth demonstration, which was moreover a double miracle, as both of his eyes were cured. Since his early youth the pupil of his left eye had been entirely covered with a scar resulting from smallpox. An injury to the right eye later in life had put that out of commission, so that he was totally blind. Convinced that he had nothing to hope from the masters of medical science, he had recourse to the intercession of M. de Pâris. He was cured in two sessions, April 22, 1733 (Figs. 12 and 13).

The seventh miracle is one of the most instructive, for it is an example of ulceration of the skin, more particularly of the nipple, a clinical sign of malignant tumor of the breast, which is very uncommon in hysteria. Demoiselle Coirin, an attractive young woman, if we may judge from the portrait which purports to be of her, had two falls from a horse in 1716; the second time she fell with full force on a heap of stones, striking the left side of her abdomen. Three months later her left breast began to swell, and all the successive symptoms of cancer declared themselves, the inflammation finally surrounding the nipple, which fell off. Two years later paralysis of the whole left side declared itself, and in 1720 surgeons wished to operate, but her mother objected, convinced that her daughter was doomed

Fig. 11.—Philippe Sergent; recovered.

(Fig. 14). She remained in this state until 1731, fifteen years, and then, after touching the shirt of François de Pâris and applying some earth from his tomb to her breast, she made a complete recovery in the night from the 12th to the 13th of August. The nipple even grew again, although it always remained smaller than the right one. She arose on the morning of her deliverance and made her toilet. Her servant brought her breakfast but wouldn't leave it because, she maintained, her mistress was ill and in the adjoining room (Fig. 15). She was convinced only on seeing the empty bed. No detail is too trifling and no evidence too puerile for M. Mongeron to pass it by.

The sequence of events in this case would seem to have been hysterical attacks of syncope, blue edema of the breast, causing gangrene of the nipple, secondary infection of the wound, hemiplegia, and inactivity atrophy, all of hysterical origin. Hysterical gangrene is very rare, but a number of authentic cases are on record.

The last miracle of Volume I. is the most dramatic. Miss Hardouin, completely paraplegic since 1725, and hemiplegic since 1730, and having lost entirely the faculty of speech for many days, was carried to the tomb on the 2d of August, 1731 (Figs. 16 and 17). She fainted in the armchair in which she was being carried to a carriage, so they had to forego that means of transportation and carry her. On being put upon the tomb on the 3d of August, all her members paralyzed, she was seized with a typical hysterical convulsion and almost immediately recovered her speech and the use of her extremities.

The sudden recovery of function after a hysterical crisis, such as a convulsion, is not at all uncommon. One thing that strikes even the casual reader is the duration of many of the symptoms. In the case just related the paraplegia had existed

six years. It had set in with violent symptoms and "attacks of apoplexy" when she was 20 years old. These attacks, which were in reality hysterical crises, *i.e.* syncopal and convulsive, were of frequent occurrence during the next six years until her deliverance.

The next miracle is one that does not lend itself so readily to interpretation. Marie Carteri had been reduced by two lacrymal fistulæ to such a state of weakness, insomnia, and pain that life was a burden. Finally caries of the bone developed and the left side of the face became enormously swollen (Fig. 18). She was cured on the fourth day of September at the tomb of the sacred deacon. All the pain disappeared. The next morning she noted on removing the bandages that the size of the fistulæ was much less and that the only reminder of the previous eye trouble was slight redness. At the end of eight days all trace of it and of the fistulæ had disappeared and she worked in the fields with a strength that she before had not known (Fig. 19). Five representations of her are given, two before and three after the miracle. Whether or not occlusion of the lacrymal ducts is of hysterical origin I do not know. That occlusion of these ducts may be overcome without supernatural intervention or without invoking aid of any kind is known.

In bringing Volume I. to a close the author gives a long disquisition on miracles and attempts to sweep aside the objections that have been made to the verity of those related. Miracles, he says, are the voice of God. It is by miracles that God communicates with man and makes His presence visible. It is by miracles principally that Christ proved His divinity. It is by miracles that He has promised to preserve and sustain until the end of time the sacred trust of faith, and, finally, it is by miracles in times of doubt and trouble in the Church that God has made known in a most striking manner what the real truth is. All of which should be construed to mean that God was on the side of the Appellants, in the opinion of M. de Mongeron; but apparently M. de Mongeron was in error.

It was evident that the cause of the Jansenists was not being advanced by the so-called miraculous occurrences. Despite the apparently overwhelming interest in the tomb at St. Medard the bulk of the population, or at least that portion of it that constitute the *vox populi*, did not take the miracles very seriously. Whether or not all that denied the verity of them were Acceptants cannot be said, but there were many who by virtue of their positions had much to do with shaping public opinion who made fun of the whole business. Meanwhile miracles began to be effected at the graves of other sainted Appellants; and gradually a change came over the entire subject.

Volume II. contains a long, fervent prayer, a dissertation on the authority of miracles, and a detailed account of four miraculous cures. The case of Anne Augier is the most interesting, for it shows how severe hysterical lesions may become and how quickly all indications of such lesions may disappear.

The miracle was wrought at the tomb of M. Rousse, priest and canon of Avenai in the Diocese of Reims. Anne had been paralyzed for more than twenty years, consumed by a cancer of the breast for seven years, infected for two years through a fistula which opened from the axilla, and tormented for a long time by an infinite number of other complaints. The way in which the paralysis developed is typical of hysteria. "This pious girl, then 25 years old, being in the parish church of Mareüil, absorbed in the divine service that was being celebrated, was suddenly stricken with paralysis of both legs and fell to the floor as if dead. Never from that moment did she have any use of them." When surgeons examined her they found entire loss of sensibility in the lower extremities as well. This discovery created a sensation among her friends and acquaintances and she was often demonstrated as a human pin cushion. At the end of eight months her legs had wasted so much that they were only skin and bones. In addition she suffered from crises which deprived her of consciousness for three or four days, during which time she would take neither food nor drink. Anne had been in this state, and worse, for fifteen years, and her appearance and general condition were so repulsive that they beggared description, but this did not deter a

Fig. 12.—Pierre Gautier de Pezenas; ill.

Fig. 13.—Pierre Gautier de Pezenas, recovered.

chevalier d'industrie, who passed her home, to covet possession of her. Despite her resistance, which was so great that she got cancer of the breast from one of the blows that he rained upon her, she became pregnant. The misery and agony of several years we pass over. She made all sorts of efforts to get

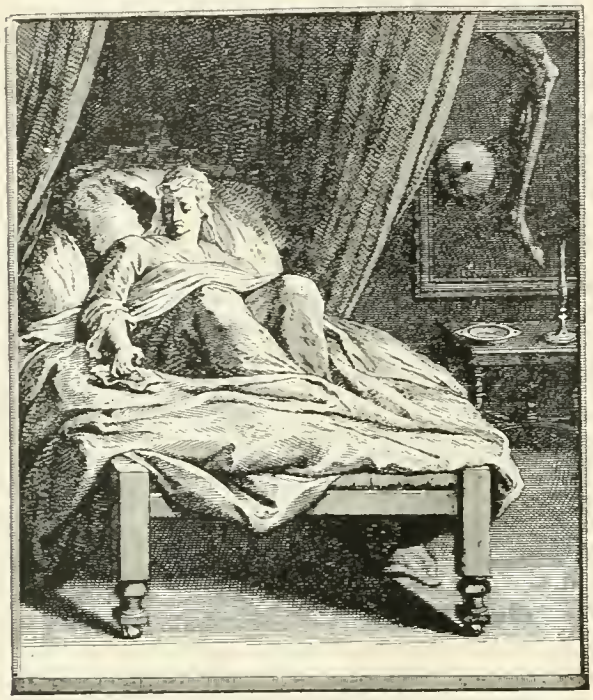

Fig. 14.—La Demoiselle Coirin, ill.

Fig 15.—La Demoiselle Coirin; recovered.

healed, but without avail. Finally she was placed in a basket, laid on an ass' back, and, supported by two lusty youths, she was brought to the tomb of M. Rousse. The picture she presented was most striking: Visage pale, livid, and cadaverous, eyes half open from weakness and defection, her head hanging limply and without strength to hold it; the body bent in a semicircle; the clicking of her bones as they struck one another was audible to passers by, and she made a terrorizing impression on everyone, many of whom asked "Where do you take this dead girl?" The illustrations depict her being brought thither and kneeling on the tomb of M. Rousse behind a priest who is saying mass. At the moment of the offertory her shriveled legs are released and she is cured. In one corner her visit to the Abbess of Avenay, who was a doubter, is depicted, and in another her restoration to full strength and health is testified to by her work; threshing grain.

Her cure caused a great furor. Gentlemen, peasants, ecclesiastics, laymen, judiciary, all came, save the Abbess of Avenay. She said it was against the law, but she had to admit the cure, nevertheless.

She was discomfited because Anne would not say she had prayed to a saint, not to an Appellant, but Anne would have none of it. She stayed eight days after her restoration, then walked home, a two-day journey. There she received an ovation that must have been very gratifying if her hysterical disposition had not been cured as well. Verily, her strength was the strength of stones, and her flesh was of brass!

The next cure related was of a much simpler state of affairs, and much more typically hysterical.

The Dame Stapart had been paralyzed for ten years in the left eye, which, from obstruction and atrophy of the optic nerve and other nerves, had lost its capacity for seeing, moving, and feeling. She also had constant headache, and finally lost the use of one arm and one leg (although it is not at all clear that she was hemiplegic). She was carried to Avenay on the 16th of May, 1828, to implore the intercession of M. Rousse. The ardor with which she prayed in the church before going to the tomb made them suspicious, and she was refused communion. The same day she went to the chapel in which M. Rousse was buried but admission was refused her. A small boy who was about to show her a secret way was pursued by his schoolmaster and given a trouncing. At this moment God cured the lady, all of which is graphically set forth in the illustrations.

The scene again shifts back to Paris, and now a new element is introduced into the *modus operandi* of the cures. Up until this time they had been wrought with great simplicity. The individual made a nine-day meditation, implored the intercession of the sainted deacon and kissed the earth in which he was buried. Sometimes they applied the earth to the apparent seat of their ailments. Then the cure occurred suddenly or gradually. In 1731, however, cure seemed to flow directly out of convulsions. Among the first of these cases was that of Miss Fourcoi. She had been cured once of dropsy by convulsions, but a deformity and contracture of her left foot had remained. Five surgeons had testified that the ankylosis was incurable, but she went into a convulsive state at the tomb of M. de Pâris and when she came out of it she was entirely cured.

Convulsions, especially what may be called the epidemic variety, have usually been attributed to demoniacal possession. Such attribution, and the attempts made to overcome it, constitute the foulest blot on the pages that record the progress of man in the era of modern civilization. In 1731 the Appellants interpreted convulsions as the intervention of the Divine Spirit, and from this time until the 27th of January, 1732, when an ordinance of the king closed the cemetery of Saint Medard not only to visitors, but for purposes of interment, the con-

vulsionists had the center of the stage. That these convulsions are the most typical of the epileptoid and contorsionist periods of major hysteria one may fully convince himself by examining the writings of M. de Mongeron and comparing them with the writings of Charcot, Richer, Gilles de la Tourette, *et al.*

A typical case of hysterical deafness is that of Catherine Bigot, who, it is said, had always been deaf and mute. Her deafness was so complete that she could not hear the slightest noise when a pistol was shot beside her ear, "evident proof that the tympanum and the nerves necessary to the hearing of sound had never been formed in her head." When she was placed on the tomb of M. de Pâris she was seized with movements of extreme violence. On the fifth day she became unconscious. After the convulsions and during the time of unconsciousness "God formed an organ of hearing in a perfect way." As soon as she recovered from this unconsciousness she understood perfectly and repeated everything that was said to her. The instant she was placed upon the tomb her face became pale, as if dead, she swooned, and a moment later she was seized with movements of such violence that she could scarcely be restrained. She showed by her appearance and her gestures that she was suffering most violent pains in the head, ears, and chest. Her head turned from right to left with such prodigious rapidity that one could no longer see her features, and the color of her mouth seemed to irradiate her entire face. Her companions, afraid, took her away from the tomb, but the deaf mute soon made it known she wished to be put back. The character of the testimonials is above suspicion. A description of the convulsions that occurred is taken from a letter written by the Bishop of Senez, who was a man that M. de Mongeron held in high esteem. "The object that struck one most forcibly and which held the eyes and the mind in astonishment was the spectacle of convulsions and violent agitations which took possession of the patients the moment they were put upon the tomb, and which ceased the moment they were taken off, and which began anew when they were put upon the tomb again. These patients were nearly always accompanied and observed by a great number of physicians and surgeons of renown, who studied the phenomena with much attention and assiduity. "Naturally," says M. de Mongeron, "such carefully trained observers were always on guard against surprise, imposture, and imagination—a bone to the watch-dog of the infernal regions. They utilized the opportunity of their thousand experiences in order to discover the source and the origin of such extraordinary agitations. They consulted together on everything that passed before their eyes, they mutually communicated their views and their reflections; the result of it all was the conclusion that convulsions and the contortions were supernatural manifestations, the work of God, and mediated through the virtue of the tomb."

The contagiousness of the disorder made itself distinctly manifest only when the king closed St. Medard. The element of persecution then forced itself into the distorted minds of the convulsionists and its effect was the same as that of a spark in a powder magazine. M. de Mongeron says that when they began to persecute the convulsionists, attacks increased enormously, and persons on every side, many of whom had never been ill, became affected. Thus the Lord displayed His bounty and His prodigality. He opened the mouths of a multitude of infants and of simple and ignorant persons, and from them came beautiful discourses, and warnings concerning the future that had the import of prophesy. Not only did these young convulsionists pronounce their discourses with dignity, but their visages, their gestures, and their attitudes portrayed in a keen and striking manner the various sentiments embodied in the discourses. Often, indeed, it was noted that the convulsionists became the living portrait of the passion of Jesus Christ. They held their arms as if upon the cross in an immobile manner, while the representation (which is the name they give to attitudes of passion) and the entire attitude of the body took on the features of the crucifixion. The lively and tender pains supported

Fig. 16.—La Demoiselle Hardouin, ill.

Fig. 17.—La Demoiselle Hardouin; recovered.

with the most heroic patience and the most perfect resignation was characteristically depicted in the leaden visage, the dying eyes, and the agitating thrills of the body. After remaining in this state for a long time a deathlike pallor covered the entire visage, the lips became withered and bluish, the most necessary to be on guard lest they be used for immoral purposes, and particularly convulsionists of great simplicity and confidence should be safeguarded." He further points out that the devil is constantly roaming about looking for innocent and tender convulsionists to devour, and that the com-

Fig. 18.—Marie Carteri; ill.

Fig. 19.—Marie Carteri recovering and recovered.

light of the half-closed eyes seemed entirely to go out, and the head, no longer able to sustain itself, fell upon the chest. Once even the author saw the tongue so completely retracted into the throat that one could see no part of it in the mouth, which remained half open. The supernatural is more marked and more striking in the living pictures which pass before our eyes of the tortures that had often to be endured by the disciples of the prophet Elias; pictures which are scarcely less calculated to excite our piety than those that set forth the suffering of our Divine model.

The third volume is devoted largely to explanation and defense of the convulsionists and to an attempt at interpretation of the "Secours Violens." After the convulsionists had reached a certain stage of development, *i.e.* after their antics had become most bizarre, it dawned upon them and upon their sympathizers apparently that they were given strength, resistance, incapacity for injury and violence, that could be accounted for in no other way than on the supposition that it was a divine emanation. As M. de Mongeron puts it, "God puts prodigous strength into certain convulsionists so that even the tenderest fibers, and the most feeble and delicate persons are able to withstand the most violent blows." God does this in order to make evident His divine might and mercy. That which He gives them the French call *secour*, and which we must translate as aid or succor, and of this *secour* there are two kinds, the little and the big. The little *secour* consists of touches, pressure, trifling blows, all of which are administered on certain parts of the body. There can be no doubt that oftentimes they mediate lubricity, for the author says: "In regard to the 'aids' which are capable of exciting concupiscence, either in the convulsionists themselves or in those who give the 'aids,' it is mon way of devouring them is to deprive them of their virginity. Even in those days, as in the days of Job, Satan came from going to and fro in the earth, and from walking up and down in it!

Grand secours, or violent "aids," which consist of blows with a hammer or mallet, pieces of iron or wood, and blocks of stone, thrusts with swords and other sharpened instruments, nailing on the cross, etc., were apparently very much used, and the illustrations of the third volume depict many of those. For instance, the frontispiece illustrates a lady known as La Petite Aubigan giving her left leg, which has a curvature, evidently due to a spasm of the peroneal muscles, a whack with a mallet, which cured it. It bears the legend quoted from Deuteronomy, "I wound and I heal."

The second illustration is that of Madeline Durand, who had a cancer of the mouth. The first picture represents her with an enormous edema of the mouth, while the second one shows her clipping a part of it off with a scissors. Then she immediately became cured. On the opposite side of the page is M. Fournier, the surgeon who pronounced her disorder beyond his aid, sitting in his study marveling at the transformed picture which Madeline presents, for now she is represented as a most attractive little creature.

The third illustration depicts a series of "aids" given to Gabriel Moler, and a wonder Gabriel must have been. The first represents her on her knees and beside her a powerfully-built young man, who wields the big stick which he is apparently about to bring down upon her head, while a number of observers stand around in various attitudes of awe and consternation. The second represents her lying flat upon the floor while two men are placing a rock, about as large as her body, upon her head. The third represents her lying on her back, a gentle-

man on his knees above her thrusting a long sharpened instrument into her abdomen, while in the fourth she occupies the center of the stage and a number of ladies and gentlemen about her are pricking her body in various places with swords, a procedure which she seems to enjoy. It is not possible here to give in detail all the manifestations of hysteria which this remarkable creature gave until she finally became cured. The illustrations depict them quite as well as words.

"It is evident that it is by violence or *grand secour* that it is pleasing to God to stop the pains of the convulsionist, to restore their shrunken limbs, and to overcome and cure their maladies. It is also pleasing to Him that proof of these aids should make a strong impression in other persons. Therefore, the most violent aids produce not only the effect of stopping the suffering of the convulsionists, but they represent symbolically the light, the faith, the courage, the confidence, love, and desire of eternal salvation in the souls of others. I have already shown in my first proposition that God makes use visibly of these terrible aids to operate many of his most marvelous cures. There have been seen any number of emaciated and useless infants acquire a regular symmetry, badly constructed bones become straight, too short bones elongated, humpbacks disappear, enormous hips become small, legs and feet form even after the age of fifty years, and absolutely incurable maladies cured by means of *grand secour.*"

The emotional equivalents of these aids constitute an important feature of the occurrences.

The stage known as ecstasy, into which the convulsionists pass, especially those who receive the *grand secour*, corresponds with the ecstasy of hysterics and cataleptics of the present day. In these ecstasies, at least in those which are marked by the most dictinctive traits, the convulsionists are suddenly struck by the unanticipated aspect of some object the sight of which ordinarily fills them with joy. They eagerly fix their gaze and their hands on high. They jump toward the heaven, they appear to wish to fly there. To see them absorbed afterwards in profound contemplation one would say that they were admiring celestial beauty, their faces illumined by a sparkling and brilliant fire, and their eyes, which one cannot force them to close so long as the ecstasy lasts, remain always immobile, open, and fixed upon that which occupies them. They are in some way transfigured, they apear to be quite different; even those who are not in this state, those who normally have something low and repulsive about them, change so entirely that they are scarcely recognized. Their exaltation has nothing which does not edify, nothing which does not inspire piety, nothing which does not lead to God. This supernatural state represents vividly in the person in which it develops, so detached from everything that is only terrestrial and transitory, a soul which aspires only to supreme happiness, a state of bliss which one might say it is already enjoying. Frequently it is during this ecstasy that convulsionists make their most beautiful speeches and their principal productions, but they speak in varying languages when they discourse the secrets of hearts, and even sometimes make them a part of their "representations."

M. de Mongeron says: "In the strongest of their ecstasy many convulsionists make speeches in an unknown or varying language. I should add that they do not themselves understand the sense of it at the instant and while they are pronouncing it, and they do not recall them, except, perhaps, in a general way, after the speeches are finished. The only proof that we have that they understand what they utter is that often they express in the most vivid manner the sentiments contained in these speeches, not only by their gestures, but often by the attitude which their body takes and by the expression of their faces, upon which the different sentiments are expressed—traits and characters of the most striking kind. The greater part of these speeches are a prediction of the coming of the prophet Elias, the trials that they have made Christ as well as his disciples, the conversion of the Jews, and, finally, of the establishment of religion over all the earth. It has only been necessary to discover that these subjects in an unknown language were for the most part prophesies of great events; to conform the different expressions that have been seen upon the faces of convulsionists while they are making their discourses, and the gestures with which they have accompanied them, with similar impressions and parallel movements that have been made by them while they were pronouncing their discourses in French, in which they have announced events which have been confirmed by the declaration of many convulsionists to appreciate the depth and significance of their discourses. Moreover, many inspired ones improvise without presenting signs of ecstatic rapture. The explosion of a simple hysterical crisis suffices to throw them suddenly into a sort of intellectual exaltation, whose accompaniments force them to give vent to their ideas. In these moments the over-excitation of the nervous centers of the brain give them the capacity to externalize their discourse with a fluidity of expression, a wealth of figures and of imaginery which does not fail to produce a lively impression upon the populace who follow the convulsionists. In convulsion their soul is much more detached from their senses than in their natural state. It is a well-known fact that convulsionists have much more mind, penetration, and intelligence while in convulsions than in their ordinary state. One sees often extremely timid girls whose makeup is but ignorance, stupidity, and low birth who, as soon as they are in convulsion, speak, nevertheless, not only with great exactitude, but with fire, elegance, and grandeur, freed as they are from the corruption of man by original fire. One can recall a multitude of facts which prove incontestably that the ordinary effect of the convulsion is to give to the soul more light, activity, more facility to conceive things, even the most elevated. A young child not in convulsion was first so timid and so terrorized that one could not get a single word out of her, and she appeared to be almost an imbecile. However, as soon as she was in convulsion she responded to everything with so much alacrity and justice that one would have taken her for a person who had great natural talents and a most perfect education.

It has been abundantly shown by trustworthy historians that in many instances the discoveries of the convulsionists were neither chaste nor edifying. M. de Mongeron thinks these were either the result of an overheated imagination or the suggestion of the devil.

The deportment of some of these individuals known as *grand secours* is to be gathered from the descriptions which the author gives of others besides those here mentioned.

A convulsionist of the first order was holding a very beautiful discourse in an unknown language. At the same time she assumed a most remarkable attitude. The body was bent backward to form

an arch, supported on the head and the heels. In this position she said a mass from one end to the other with peculiar dignity, but in an unknown language. She then extended herself upon the ground on her back, occasionally agitated so profoundly that it was necessary that someone should hold her feet, to watch and to prevent all intimacy, and to hold down her clothes. The convulsionist recited a De Profundis in French, but before reciting it she asked that they put her head down and her feet up in the air. After having recited with great demonstration of piety this prayer she wanted them to help her throw a somersault in the air, and was so little embarrassed that she was keen to have them help her do it again. Finally she said, with great unction and gratitude, that what she had just done was a mystery to be interpreted symbolically and represented the topsy-turvy state of matters in the Church. A convulsionist named The Invincible chanted praises to God while making somersaults. Poncet saw a convulsionist who said her prayers while pulling out the tongue like one possessed, and upon whose face was displayed the most horrible contortions. He had seen another whose exaltation seemed to come from despair who was transported by the convulsion to tear her face with her nails and to throw herself out of the window. Nothing was more striking, according to Lataste, whose "theological letters" is a reliable source of information, than the manner with which convulsionists asked miracles of God; sometimes they prayed to God while clipping the hair, while eating soup, or while doing a thousand other banal things. Sometimes they prayed while choking themselves to the point of putting out the tongue, while hanging from a hook with a cord around the neck, while being beaten upon the back or upon the belly, while being pushed and pressed and balanced, sometimes while having their arms, legs, and breasts pulled, while twirling, their heads down, their legs in the air, while giving a thousand other signs of indecency to persons not only of their own sex but to men. Such conduct was not confined to the laity; religious people and ecclesiastics participated as well.

"At St. Medard," says Lataste, "one sees men pray for their health in shaking rudely their heads, in clapping their hands, in shaking wildly their legs, and tormenting themselves like real demons. I have seen there women who implore miraculous cure while running about like a mad person or one possessed. Others sit upon men's knees or extend themselves at full length upon the tomb of Pâris in a most indecent way, situations which often disconcert the modesty of spectators. Others are held up by the middle by men who let them fall or pirouette them from time to time. A preacher remained extended upon the ground in preaching most sublime sermons. From time to time he lifted his feet, which he placed upon another convulsionist. The consulting doctors," adds Lataste, have records that it is in that moment that the convulsionist makes beautiful discourses, touching prayers, edifying representations. At the same moment that they make all these things they are doing indecent somersaults in the air with very disgusting attitudes."

In 1845, *i.e.* soon after this work of Carre de Mongeron was completed, public interest in the convulsionists began to die out. Their antics and gyrations ceased to be a matter of wonder and their conduct became offensive, and, in some instances, intolerable. There is much evidence from reliable sources to show that many individuals utilized it as a means to lubricity through unnatural channels. After general interest in them had ceased, and more particularly after many of the most conspicuous Secouristes had been thrown into prison, the Church—meaning the Acceptants—frowned very severely upon anything in the shape of violent aid, and the epidemic was over.

Studied in the light of our present-day knowledge of the clinical manifestations of hysteria, there is very little in the records of the miracles wrought at the tombs of sacred Appellants or by "Secour" that transcends our understanding. The investigations of neurologists, and particularly those of France, have shown that the subjective and objective symptoms which the various individuals whose histories are related in such detail by M. de Mongeron, are those that constitute the signs and the symptoms of the "attack" of the disease. These signs have such definite characteristics and associations that they are rarely to be confounded with those of organic disease. Such characteristics and associations are to be found in every case related *in extenso* by de Mongeron. The "representations," the ecstatic states, the epileptoid state, the state of contortions and passionate attitudes, and the state of delirium, which are described in such detail in the volumes that we have been examining, are no less and no more typical and characteristic than those described in such monographs as that of Paul Richer on major hysteria.

After an examination of these volumes and of similar literature of previous centuries, one reads with amazement the statements of strayed theologians and semiphysicians, that functional nervous diseases are increasing rapidly at the present time. They cite in substantiation of such alleged increase the fact that psychasthenia was not to be found in any standard dictionary until 1901, and that neurasthenia came into being only a generation ago. If their opinion and judgment concerning existing conditions are no more reliable than those of the past, they need not be taken very seriously.

RECURRENT AND ABDUCTOR PARALYSIS OF THE LARYNX.

INTRODUCTORY REMARKS ON ANATOMY AND PHYSIOLOGY; ETIOLOGY OF PARALYSES OF CENTRAL ORIGIN.*

By J. W. GLEITSMANN, M.D.,

NEW YORK.

The subject, selected by your Council for general discussion, is in my opinion the most interesting and at the same time the most difficult one in the whole domain of laryngology. It is interesting, because it leads the laryngologist at once beyond the sphere of his specialty, and it is difficult, as it deals with the most intricate questions of neurology, about which in many instances the investigators entertain conflicting opinions.

For a full understanding of the part assigned to me—the central causes of recurrent and abductor paralyses—a clear conception of the motor centers in the cortex and bulbus, of their predominant functions, their connecting strata is absolutely necessary. With the approval of your presiding officer I shall briefly analyze the anatomical features and add such physiological and pathological data, which have a direct bearing on our subject.

Anatomy.—The larynx has to perform two functions, diametrically opposite to each other, viz., phonation and respiration. The chief center for

*Read before the American Laryngological Association at the thirtieth annual Congress, Montreal, May, 1908.

phonation, adduction of the cords and a voluntary act is in the cortex: for respiration, abduction of the cords, and a vital process, in the bulbus. In addition there are subordinate centers in reverse order and of lesser dignity for phonation in the bulbus, for respiration in the cortex. The connecting

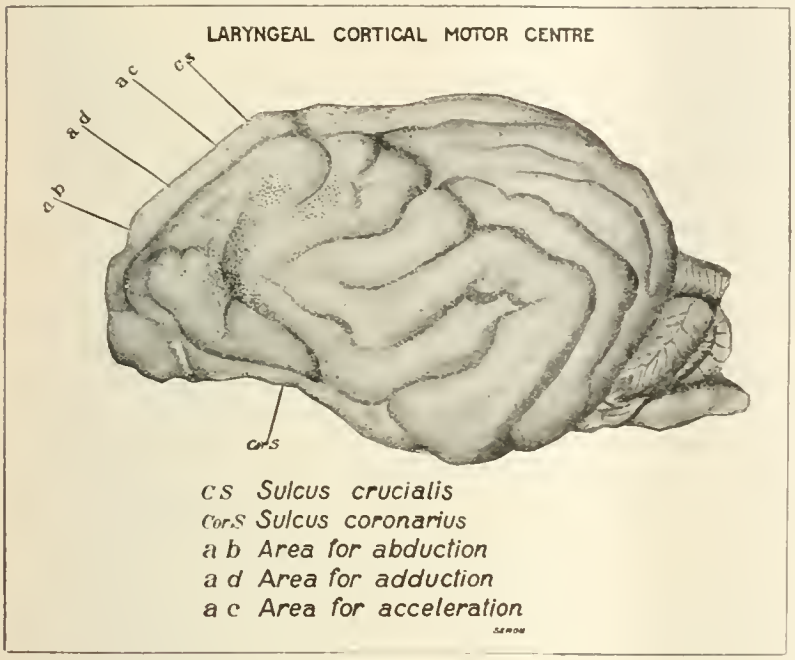

Fig. 1.

nerve fibers run from the cortical to the bulbar center and vice versa through the internal capsule.

The cortical motor center for phonation was discovered by H. Krause[1] to be located at the descending surface of the prefrontal convolution. The result of his investigations was confirmed by Semon[2] and Horsley,[3] who by extending their researches found additional motor areas in the cortex for acceleration and for deepening of the respiration. By ingenious experiments Risien Russel[4] succeeded in finding below the phonatory center a locality from which abduction of the cords can be elicited. The illustration of the different cortical motor centers is from Semon's treatise in Heymann's Handbook of Laryngology and needs no further comment.

The bulbar representation of the larynx is in the fourth ventricle, and we find in the alea cinerea two localities, irritation of which produces typical abduction of the cords, the respiratory act, further smaller areas for bilateral adduction, one for unilateral adduction, and one for the cadaveric position of the cords, all of which are graphically shown in the illustration, which is also taken from the same treatise by Semon.

The existence of the subordinate centers, mentioned above, has been proven by repeated experiments on animals, of which one only will be cited. Acephalic monsters, animals whose brain has been extirpated, are able to utter a cry, due to the subordinate phonatory center in the bulbus, but their respiratory movements are not materially influenced, confirming the bulbus to be the main center for respiration.

These elementary anatomical data, condensed within the narrowest possible compass, have almost universally been accepted; the first real discrepancy of opinions we meet is about the question of the root of the motor nerve of the larynx, which is not definitely decided at the present day.

After the careful experiments of Schech[5] the laryngeal motor nerve was for many years considered to have its source from the inner branch of the accessory willisii, till Onodi[6] and Grabower[7] [8] brought forth forcible arguments in favor of the pneumogastric, exceptions to which were taken by some authors. But a recognized authority, H. Oppenheim, says (1905) in his book[9]: there is at present no certainty in regard to the participation of the accessory nerve in the innervation of muscles supplied by the pneumogastric.

Another much debated issue relates to the nature of the recurrent nerve. While many investigators strongly believe it to be exclusively a motor nerve, others offer good reasons, based on animal experiments, to consider it a mixed nerve, carrying also centripetal fibers. But if the latter view should prove to be correct, we cannot yet draw any definite conclusions from it in regard to the human system, as even in animals a differentiation exists in the response in different species.

The last and a most important anatomical fact is the discovery by Risien Russel[10] of the existence of special nerve fibers for adduction and abduction, which run in separate bundles throughout the whole

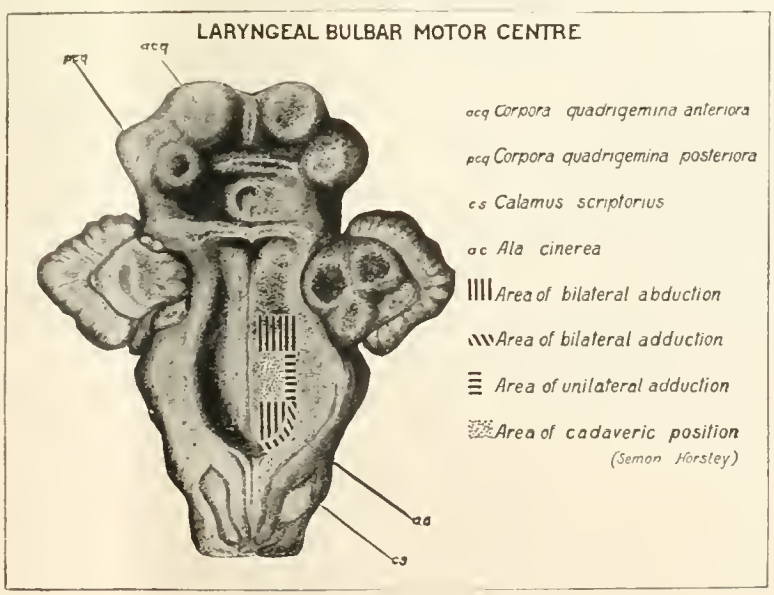

Fig. 2.

course of the recurrent, those for the abductors on the inner, those for the adductors on the outer side of the nerve trunk. They can be dissected to such an extent that one set of fibers responds to electrical irritation exclusively by adduction, the other

exclusively by abduction of the vocal cords. By his work the formerly vexed question was solved, how a supposedly homogeneous nerve could effect such directly antagonistic movements.

Physiology and Pathology.—The cortical motor centers of the larynx differ from other cortical motor centers in the essential point that irritation of either one is always followed by symmetrical bilateral adduction of the cords, phonetic movements, which also take place, when one cortical center has been destroyed by disease or experimentally removed. This physiological observation had enjoyed universal acceptance, till Masini[11] maintained to have found a locality in the cortex, from which movements of the opposite side of the larynx could be produced. Subsequent experiments by others did not verify his statements, but recently Katzenbach[12] obtained by an improved method similar movements of the corresponding as well as opposite side.

The influence of the bulbar center on respiration and on the position of the glottis has been carefully studied by Semon[13] in his endeavor to ascertain if the vocal cords play an active part during quiet respiration, and to determine the cause of the difference between the width of the glottis during life and its cadaveric position after death or after severance of the pneumogastric or recurrent. He found by numerous and carefully made measurements with graduated mirrors, that in over 80 per cent. of adults the glottis remains stationary during quiet respiration and is considerably wider than in the cadaveric position. Its average width in men during life is 13.5 mm.; after death 5 mm.; in women 11.5 and 4 mm. respectively. Without entering into a detailed statement of his experiments and arguments, he is led to the conclusion that the greater width of the glottis during life is the result of a permanent activity of the abductor muscles, due to tonic, rhythmic impulses, received by their ganglia centers in the medulla from the neighboring respiratory center through centripetal fibers of the pneumogastric. He calls this physiological action of the abductor muscles the abductor tonus.

I cannot conclude my introductory remarks without calling your attention, and emphasizing the far-reaching importance of the proclivity of the abductor muscles to paralysis in progressive organic lesions.

While Rosenbach[14] on the strength of a case of cancer of the esophagus, accompanied in the beginning by paralysis of both abductors, later of both recurrent nerves, was the first to proclaim that the abductors are the first to suffer from compression of the recurrent, the credit belongs to Semon, to have proven that this important pathological condition is seen not only in local lesions, affecting the nerve along its course, but also in central, cerebral as well as spinal diseases of an organic character.

His first publication[15] appeared (1881) in an American journal of high standard, devoted to our specialty, but meeting with a premature death on account of the indifference of the laryngologists at that time, viz., the *Archives of Laryngology*. His statements met with a host of opposition and elicited controversies, sometimes of an acrimonious character and not always of the highest scientific standard. By his incessant labors, extending from 1881 to 1897, and by publications too numerous to quote, he had finally the satisfaction to have the so-called Semon Law universally acknowledged. It is beyond the scope of these remarks to enumerate the arguments he put forth to support his assertion, the truth of which all of us had undoubtedly frequent occasion to confirm.

The ultimate true cause of the proclivity of the abductors to paralysis has not been definitely determined yet. Grabower[16] sought not long ago to solve the problem by anatomical, instead of experimental researches, previously employed. He examined the innervation of the laryngeal muscles in regard to the configuration of their last nerve terminals, and counted the number of nerve fibers in each muscle. He found that the branch for the abductor does not divide into smaller ones, radiating in different directions, as in the adductors, and that the number of nerve fibers is less in the former than in the latter. The posticus f.i. has in the average 281 terminal fibers, the external and internal thyroarytenoid 485, the transversus 279, and the sum of all the adductor fibers is 680.

I have so far not been able to find reports confirming Grabower's investigation, but without feeling competent to pass on its merits, I am free to say that I would consider it a most acceptable solution of the question at issue. It would explain also in a natural way by an anatomical anomaly the first and only exception to Semon's statement during the long period of twenty-five years, observed by Saundby[17] in a case of esophageal cancer, the analysis of which I have to leave to the gentleman treating of peripheral causes.

Semon[18] admits frankly the facts in Saundby's case, but is not able to offer an explanation. On the occasion of his visit to the United States in 1904 I called his attention to Grabower's publication, but the same seemed not to appeal to him. He adheres to his belief in the biological differences in the structure of the laryngeal muscles and nerves, which is evident from experimentation in young and in old animals as well as in different species, and still more from the differential influence of superficial and deep narcosis on the recurrent, which our late member, Hooper,[19] was the first to investigate.

Etiology.—Recurrent and abductor paralyses of central origin are caused by organic affections, while cortical paralysis of a functional character occurs in hysteria, psychical emotions, shock, etc., with concomitant paralysis of the adductors, but not of the recurrent proper.

According to the location and the nature of the diseases we can distinguish paralyses due (1) to cortical lesions, (2) to disturbances of the nerve tract in the internal capsule between cortex and bulbus, (3) to bulbar processes, (4) to syphilis, (5) to tumors, exostoses at the cranial base, pressing upon the pneumogastric, (6) to spinal diseases, (7) final paralyses of the Avellis and Hughling Jackson type.

Beginning with paralyses due to cortical lesions, we enter at once a much contested field.

A number of cases have been published, in which their authors claim that an unilateral cortical affection had caused an unilateral organic paralysis. Whilst in many instances the history, the laryngeal examination, the post-mortem reports, are incomplete or missing, and therefore the proof of the contention made is lacking, there are cases in which the symptoms in the living corresponded with the lesion found after death. Garel,[20] for instance, saw a woman, seventy-three years of age, with hemiplegia of the right side and complete paralysis of the left vocal cord. The autopsy showed softening of the left hemisphere and two similar foci in the right one at the base of the third frontal convolution, to the latter of which Garel attributed the laryngeal paralysis. A microscopical examination of the bul-

bus had not been made, and consequently its integrity cannot be vouchsafed.

On the other hand, cases which appeared during life to belong to this class show bulbar disease after death. Our member, Delavan, is quoted amongst the above authors, when relating the history of his patient seen during life,[21] but in his comment on the result of autopsy he says[22] that his case was a direct proof that paralysis of the larynx of central origin is generally due to bulbar lesion and not to disease of the cortex.

In my opinion there are at the present time extremely few believers in an unilateral laryngeal paralysis brought about by unilateral cerebral disease; otherwise the number of cases would certainly be much larger than we find in the literature, as unilateral cortical lesions, for instance hemorrhage, softening, etc., are not infrequent. Semon in his article in Heymann's Handbook, 1898, could collect only twenty-five cases, in which such a coincidence was claimed by the authors. The strongest argument against the occurrence of these paralyses is the anatomical fact that laryngeal movements can be excited by each of the two cortical centers, independent of the loss or destruction of one of them, further that the experimental extirpation of the cerebral hemispheres, down to the fourth ventricle, does not interfere with the respiratory movements of the cords, the integral function of the abductor.

Affections involving both cortical centers, for instance hemorrhages, are as a rule not confined to this area alone, and are of such a serious character that the laryngeal condition is overshadowed by the grave general symptoms. But cases are reported in which the connection between the cortical and bulbar center through the internal capsule became obliterated by the morbid process with resulting aphasia.

Eisenlohr's[23] patient had general motor disturbances, was absolutely speechless, and the post mortem showed destruction of the posterior third of both thalami optici, partial degeneration of the posterior part of the internal capsule, and of the pyramidal tract of the medulla and spinal cord. Pathological changes of a similar nature were found after death and reported by Pitt.[24 25] in a case of chronic nephritis with two apoplectic attacks in quick succession, the second one being followed by loss of voice. In both cases bulbar and cortical lesions were absent, and the patients experienced no respiratory difficulties during life.

Similar laryngeal symptoms, associated with lingual and labial pareses are observed in pseudobulbar paralysis, due to disseminated cerebral lesions, in which disease of the medulla and respiratory troubles are absent, and the laryngeal muscles undergo no fatty degeneration.

The subsequent chapters can be considered more briefly, as they deal mostly with well-known data, and offer no field for widely dissenting views. Under bulbar paralyses I have included all cerebral diseases, irrespective of the primary seat being in the bulbus or in the hemisphere. Further the etiological features of recurrent and abductor paralysis will not be treated of separately, as both are liable to be caused by the same affection, and as the latter is in many instances only a precursor of the former. Prevalence of one or the other type in special diseases will be mentioned in its proper place.

Progressive bulbar paralysis, being due to a degeneration of the motor nuclei in the medulla, represents a genuine type of the bulbar origin of laryngeal paralysis. As a rule paralysis of other organs, tongue, lips, precedes the laryngeal symptoms, which appear sooner or later, dependent on how early the laryngeal nuclei are attacked. The laryngoscopic picture varies in different patients, according to the focus and the intensity of the process. Complete recurrent and unilateral as well as bilateral abductor paralysis has been observed, whilst some authors claim to have seen also adductor paralysis.

Another bulbar affection occupying the same or also adjacent areas is the apoplectic form of bulbar paralysis, caused by disease of the blood-vessels of this region, producing hemorrhages, thrombosis with subsequent softening, also embolism of the vertebral or basilar arteries. Many reported cases of cerebral hemorrhages and encephalomalacia with concomitant laryngeal disturbances are undoubtedly due to such lesions, which have been described already as early as 1879 by Eisenlohr.[26 27] If the patient survives the attack and its sequelæ, we can expect to find a recurrent paralysis, if all the motor fibers are destroyed, otherwise an abductor paralysis.

In the different forms of meningitis we observe anomalies of sensation, but seldom paralysis of the larynx. Our late member, Major,[28] saw a patient with bilateral abductor paralysis after cerebrospinal meningitis; tracheotomy was performed and the patient's condition remained stationary for seven years, when he died by an accident.

Cases of paralysis from multiple cerebrospinal sclerosis are rare, and the laryngeal symptoms depend on the extent of the disease. Loeri[29] reported several cases, one of which had recurrent paralysis, J. Solis-Cohen[30] (1886) a case of unilateral, later bilateral, abductor paralysis, shown to this Association seven years before. From the carefully made autopsy he concludes that the paralysis has been caused by an ascending sclerosis. Rethi[31] collected in a recent publication 42 cases of sclerosis from the literature and gave a full description of the subject in all its bearings.

Although infectious and toxic paralyses do not belong to the part assigned to me, I cannot refrain from mentioning syphilis of the brain as a cause of recurrent or abductor paralysis. M. Mackenzie[32] published already, 1873, one case, and Lefferts,[33] 1878, two cases of bilateral abductor paralysis due to syphilis, all three cured by specific treatment.

Tumors at the base of the brain are liable to produce paralysis by pressure on the pneumogastric. The symptoms are generally not confined to the larynx alone, as the extension of the growth is apt to implicate other nerve roots also. Nothnagel[34] communicated an exceedingly interesting case of an extended unilateral paralysis, involving the recurrent of the same side, which was due to pressure from a large abscess at the cranial base, found at the autopsy. Similar symptoms we must be prepared to meet in affections of the cranial bones, exostoses, fractures of the base of the skull, etc.

The importance and the deleterious influence of locomotor ataxia on the larynx is too well known to all of us, to need but brief remarks. General medicine is indebted to laryngology because in more than one instance the laryngologist detected abductor paralysis in an otherwise healthy person with a perfectly clear voice, and suspicion being aroused, the examination of the patient revealed locomotor ataxia. By far the most prevalent type is abductor paralysis, of which again the bilateral form is more frequent than in any other disease. Burger[35] collected in his excellent monograph 71 cases of paralysis in tabetics, covering the period from 1866 to 1891, 43 of which had abductor paralysis. Still more striking is Sendziak's[36] supplementary table of

53 cases of paralysis published between 1892 and 1898. Of these six only had recurrent; of the balance 22 unilateral and 25 bilateral abductor paralysis.

In the remaining spinal diseases we find only isolated cases of laryngeal paralysis, a few of which may be mentioned. Löri[37] observed a case of bilateral recurrent paralysis in amyotrophic lateral sclerosis, and one in acute spinal leptomeningitis, Schroetter[38] and Gavello[39] each a case of unilateral recurrent paralysis in syringomyelia, and Koschlakoff[40] a bilateral abductor paralysis in progressive muscular atrophy.

Although finding scant consideration in the textbooks, a series of unilateral laryngeal paralyses, associated with paralysis of other organs is of sufficient interest to be mentioned.

Avellis[41] was the first to draw attention to the occurrence of simultaneous unilateral paralysis of the larynx and soft palate—the genuine Avellis-syndrome. In another form the muscles of the neck are also paralyzed. If hemiplegia of the larynx, pharynx, and tongue exists, we have the Hughling-Jackson type. A typical case of the latter with abductor paralysis was demonstrated in the London laryngological society by Semon,[42] who in consideration of the general symptoms, believed it to be of central origin, due to a meningeal thickening at the base of the brain. Tapia,[43] who observed unilateral paralysis of the larynx and tongue, called it the fourth type, and finally Pohli[44] gave a complete description of the subject in the Italian Archives, 1906.

A SUGGESTION AS TO THE DIETETIC TREATMENT IN DILATATION OF THE ESOPHAGUS.

By MAX EINHORN, M.D.,

NEW YORK.

ROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

A FEW years ago I tried to improve the condition of a patient (W. B.), suffering from esophageal dilatation, where, as is well known, everything remains at first in the dilated esophagus and does not reach the stomach, by means of the introduction of a tube from the esophagus into the stomach. This

FIG. 1.—X-ray photograph of the thorax of Mrs. Sara K. after the ingestion of a glassful of milk with one ounce of subnitrate of bismuth. The dilated esophagus is distinctly visible as a dark shadow.

tube had several openings both in the esophageal and in the gastric end, to facilitate the passing of liquids from the esophagus into the stomach. Patient B. utilized this contrivance a few times, but later discarded it because he was able to press most of his food through into the stomach by means of thoracic compression.

A short time ago I had a patient with esophageal dilatation, where the usual mode of treatment (fluid and semi-fluid diet and compression of the thorax after deep inspiration) failed completely. Here the tube was used to great advantage. I will first describe the case and then sketch the method of treatment by means of the esophageal drainage tube.

March 21, 1908, Mrs. Sara K., about 40 years old, has been suffering with stomach trouble for the last six years. Her ailment started suddenly with fever, pain in bones and joints and muscles, and vomiting. This attack lasted two or three days, and has left her with chronic "stomach trouble."

Present condition. She cannot eat solid food without vomiting. She usually retains food one or two hours, and then vomits what she has eaten. It is undigested and often decomposed. She has a sour, foul taste in her mouth. Patient has never vomited any blood. She often vomits in the morning food she has taken the night previous. At night her food often comes up during sleep. Meat causes her to vomit.

She has made a practice of performing lavage before eating. At times she has slight pains over the stomach, at times cramps. Appetite is good, bowels are fairly regular. She coughs at night. Heavy foods (meats, etc.) are immediately rejected. She feels a fullness behind the sternum after taking liquid food. This feeling always disappears after vomiting. She always vomits from one to thirty minutes after taking semi-solid food and within two hours after liquid food.

The chest organs appear to be normal. The stomach is somewhat prolapsed; its greater curvature extends to three fingers' breadth below the navel. The right kidney is movable in the fourth degree. The urine contains no sugar and no albumin. Swallowing sound is absent. Examination with bougies showed that there is no resistance to be encountered through the esophagus and cardia. Bougie No. 53 passes easily into the stomach.

March 22.—A soft rubber tube is introduced into the esophagus to about fifteen inches from the teeth, and the expression method is applied, when 200 c.c. of food contents appear: reaction acid, no free HCl, and no ferments. The tube is then pushed further down to twenty-three inches from the teeth, and the expression method is again applied: 100 c.c. of chyme is obtained: free HCl is present in small quantity; rennet is present.

March 23.—Patient drinks 300 c.c. of black coffee and compresses her thorax repeatedly after deep inspiration. One hour later the esophagus is emptied (showing still 150 c.c. of coffee) and then washed out. Patient drinks a glassful of water. On percussion an area of dullness is found to the right of the upper part of the sternum. Five minutes later the tube is introduced into the esophagus (15 inches) and expression applied. There appear 200 c.c. of clear water mixed with some mucus. The dull area to the right of the sternum has disappeared. The tube is then pushed into the stomach (22 inches) and expression practised: 60 c.c. of a dark brown fluid are obtained smelling strongly of coffee and showing a positive reaction of free HCl.

March 23.—Patient drinks a glassful of milk to which 30 grams of subnitrate of bismuth have been added. Shortly thereafter an *x*-ray picture of the esophagus is taken (Fig. 1). The diagnosis of idiopathic dilatation of the esophagus without cardiac stenosis was made.

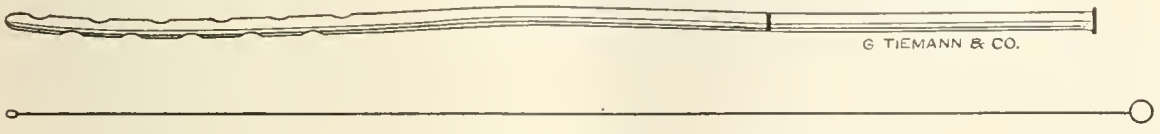

Fig. 2.—The esophageal drainage tube with stilette

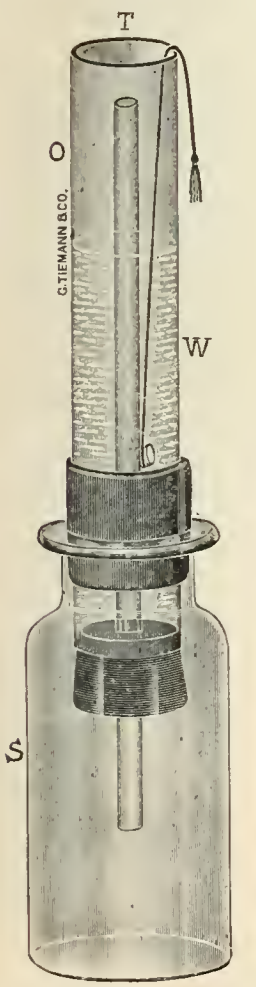

Fig. 3.—O, esophagus-cylinder; S stomach, lower bottle; T, tube inserted in the cylinder; W water.

The usual method of nourishing this patient having completely failed, an attempt was made to empty the esophagus into the stomach by means of the drainage tube, which proved very successful.

I will now describe the drainage tube as well as the principle on which it works.

If from the dilated esophagus fluids do not get into the stomach, the failure may be caused by one of two things: (1) lack of peristalsis of the esophageal muscles; (2) hermetic closure at the upper or lower part of the esophagus. The closure need not be—and usually is not—of an organic nature, and bougies or sounds do not find any difficulty in passing the entire canal. The walls of the esophagus may, however, lie in such lose apposition or may be folded in such a manner either at the beginning or at the cardiac end, that is absolutely air tight. This prevents fluid from escaping from the esophagus, just as from a pipette nothing can drop if we close the upper end with the thumb. To facilitate the drainage of the esophagus into the stomach, all hermetic closure of the esophagus must be overcome and a continuous canal between the two organs must be established.

The drainage tube is constructed in the following manner: a soft rubber tube 30 mm. in diameter and 21 inches in length is provided with a large number of apertures from the lowest part to seven inches above it. There are two marks at 17 and 21 inches from the end, and the entire tube is provided with a mandrin (Fig. 2).

The drainage tube with mandrin is introduced by patient himself immediately after taking fluid or semi-fluid food. The mandrin is then removed and the tube is moved up and down for about half to

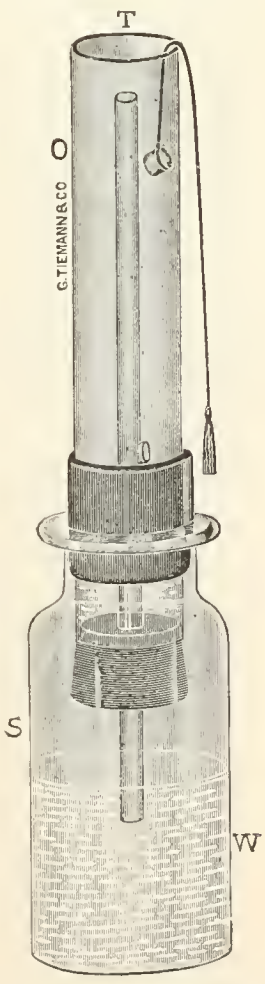

Fig. 4.—O, esophagus cylinder; S, stomach, lower bottle; T, glass tube inserted in the cylinder; W, water.

one minute between the marks at 17 and 21 inches, and is then withdrawn. Moving the tube to and fro hastens this process as it tends to eliminate the closure at the cardia.

The following apparatus represents the conditions of the dilated esophagus, stomach, and drainage tube, and illustrates the mode of its working. The lower bottle *S* represents the stomach, the upper receptacle *O* the enlarged esophagus, the stopper the closure at the cardiac end (the stopper fits air tight into the upper cylinder but not into the bottle *S*); the glass tube *T* represents the drainage tube. The glass tube has an opening and a cork (Fig. 3). If the opening is closed, the water which is poured into the upper cylinder remains there without getting into the lower vessel, just as liquids will remain in the esophagus without getting into the stomach. If the cork is removed from the glass tube, the fluid immediately flows into the lower bottle (Fig. 4). The drainage tube corresponds to the opened glass tube, and after its introduction into the stomach all fluids from the esophagus must enter the stomach.

That the drainage tube, which, by the way, resembles the Schmidt-Rimpler tube, really works as described, is proved by the following:

1. After drinking a glass of water or milk patient feels a pressure in the thorax; if the drainage tube is introduced and left for about half a minute, the feeling immediately disappears.

2. After taking about 250 c.c. of fluid, the entire amount may usually be recovered after introducing the usual stomach tube (to about fifteen inches from the teeth). If, however, after drinking the water, the drainage tube is introduced and left in the stomach for about one-half a minute, we can no longer obtain any fluid in the usual manner.

3. The patient drinks a glass of milk in which one ounce of subnitrate of bismuth has been suspended and is exposed to the *x*-ray; fluoroscope shows a shadow along the sternum (as in the photograph). Now the drainage tube is introduced and the fluoroscope shows that the shadow has disappeared.

All this seems to show that the drainage tube transmits esophageal contents promptly into the stomach. The drainage tube has been of practical benefit in the nutrition of this patient and may therefore be recommended for the treatment of similar cases.

INFLAMMATION OF THE CIRCUMFLEX NERVE.*

By CHAS. F. DISEN, M.D.,

MINNEAPOLIS, MINN.

DEMONSTRATOR OF ANATOMY AND OPERATIVE SURGERY, HAMLINE UNIVERSITY.

Pathologically neuritis occurs as perineuritis, interstitial, or parenchymatous neuritis, according as the nerve-sheath or the connective tissue between the nerve-fibers or the axis-cylinder itself is attacked. Etiologically neuritis may be spontaneous or idiopathic; it may be toxic, as from arsenic; infectious, as in connection with tuberculosis; diathetic, as occurring in rheumatic or gouty constitutions, or it may be cachectic or traumatic. The cases of inflammation of the circumflex nerve that have occurred in my practice have been caused by prolonged exposure to draughts striking the shoulder or by blows hitting across the deltoid muscle, or by overwork of such kind as sawing wood or using the sledge-hammer; also by fracture of the surgical neck of the humerus and by dislocation of the shoulder-joint. Judging from my own experience neuritis frequently follows the latter accident, and as I have seen it occur with different methods of reduction I cannot hold any particular method responsible for such a complication.

In case of dislocation or fracture the symptoms of an eventual neuritis would obviously be overshadowed by those of the injury until about three and six weeks, respectively, later, when we may find deltoid paralysis present—which, in a fracture case might be taken for functional weakness from immobilization. In other cases the patient becomes annoyed with a rather continuous gnawing pain in the shoulder region. Perverted sensations, as feelings of tingling, or burning, and numbness, may be experienced. Tenderness is felt over the deltoid and teres-minor muscles; exquisitely, if pressure be applied over the nerve lines. Slight fever may be present or not. Neither active nor passive motion of the shoulder-joint is sufficiently painful to make the patient shun work. If the character of the trouble is recognized at this early period and the arm is put at rest, rapid restitution may come. On the other hand, if the patient undertakes such work as would engage the arm in strong backward movements, the inflamed nerve is very liable to undergo degeneration resulting in deltoid paralysis. Anatomical arrangement may be responsible for the vulnerability of the circumflex nerve; at least it has something to do with the readiness with which the inflamed nerve undergoes degeneration. Recalling the anatomy of the nerve, let us consider that, as it is about to enter the "quadrilateral space," it curves directly backwards across the axillary border of the scapula, but little of the subscapularis intervening. Next it has the humerus externally, the hard triceps tendon internally, while below it is crossed by the sharp margin of the latissimus dorsi tendon (works on Anatomy say teres-major). Lastly the nerve hugs around the humerus before it terminates in the anteromedial part of the deltoid muscle. Consequently, whenever the arm is strongly carried backward, the nerve is drawn through a narrow and rigidly bounded space at the same time that a leverage is brought to bear on it across the scantily padded margin of the scapula.

Although, as we know, this arrangement and mechanism do not prove precarious under ordinary circumstances, we may reasonably infer that, with overexertion, especially in a rheumatically disposed subject after exposure, or with the presence of exudation near the shoulder-joint, the nerve may easily be subjected to a harmful strain or pressure. Now, suppose that the nerve already is inflamed from any cause whatever, and the case is only one of perineuritis, which of itself would not cause paralysis, but the patient continues the use of the arm. We should then expect inordinate swelling of the nerve and a consequent disproportion to arise between its circumference and the rigid passage-way. The resulting pressure will cause the inflammation to spread to the axis-cylinders, and we shall have degeneration and paralysis as a result. The patient now begins to have difficulty in carrying his hand up to the neck, and gradually the paralysis increases till the arm cannot be lifted from the side. The degeneration may migrate to other nerves, notably the posterior thoracic, musculocutaneous, and muscularspiral, entailing paralysis of the muscles respectively supplied. The paralyzed muscles sometimes undergo rapid atrophy.

*Read before the Norwegian Medical Club, April 14, 1908.

After about five weeks the nerves, under favorable circumstances, become regenerated, motion returns, and the wasted muscles regain their former dimensions.

Considering diagnosis it might be stated that in neuralgia the pains are characterized more by exacerbations and that in rheumatism joint-motion is more distinctly painful, while other joints also are apt to be implicated. It is expedient, however, to consider and treat as neuritis any case of suddenly appearing and then persisting pain in the shoulder region, especially when preceded by exposure or overwork of a predisposing nature. Also it is well for a patient with shoulder-dislocation that we anticipate the frequent sequel of neuritis to such an accident. When paralysis has ensued, cerebral paralysis may be excluded by examining for the reaction of degeneration, which is present in neuritis but absent in the former.

The prognosis is favorable when judicious treatment is applied. On the other hand many of us have encountered odd cases of impaired shoulder motion that are attributed to rheumatism or some injury, when probably unrecognized neuritis has been a factor.

As for treatment the first in importance is to place the arm at rest in any comfortable position that does not allow an extensive backward motion. Soothing applications, such as oily solutions of menthol and salicylate of methyl, may relieve the pain. Massage in the form of effleurage should be administered daily with long even strokes along the arm as well as over the whole shoulder-region and serratus magnus muscle. Kneading, beating, and strong currents of electricity are distinctly harmful. So are strong counterirritants and blisters during the first three weeks. If paralysis supervenes—which almost surely happens if the patient has continued to work or has received vigorous massage—we should tell him that no treatment will cure him before a month has elapsed. Yet, in order to limit the neuritis and ensure a perfect future restoration of function, we should continue with immobilization and effleurage, adding in the third week very mild descending galvanic currents. When voluntary motion begins to reappear we should administer passive movements in addition to mild galvanism and allow such gentle active movements as can be done without any special effort; also the immobilization may be discontinued, as the patient now probably is in the fourth week and regeneration is taking place. In performing passive movements it is important, especially in cases complicating dislocation or fracture, that the scapula be firmly fixed while the arm is being elevated. In many cases, whenever the arm is lifted, a powerful spasm of the abductors is reflexly induced by an irritable condition of the articular filaments of the circumflex nerve, and the scapula moves along with the humerus. If this tendency is not repeatedly opposed permanent contraction of the adductors and impaired motion may be the result. As soon as the patient can lift the arm in vertical position light dumbbell exercises may be practised until he has regained his former strength.

Dangerous Lozenges.—Chlorate of potassium lozenges are very combustible, and patients should be warned not to carry them loose in the pockets lest accidents occur. Two cases have been reported recently of men who have been seriously burnt through the ignition of chlorate of potassium lozenges whilst being carried loose in their pockets. The explosions appear to have been quite spontaneous, and not to have been caused by the proximity of wax matches, which greatly increase the danger of combustion.—*Medical Times.*

AN UNUSUAL CASE OF CEREBROSPINAL MENINGITIS TREATED WITH ANTI-MENINGITIS SERUM.

By H. N. MOELLER, M.D.,

NEW YORK.

HOUSE PHYSICIAN ST. VINCENT'S HOSPITAL.

This case is of interest chiefly in being one of unusual symptoms and course, and in showing immediate benefit obtained from antimeningitis serum at a late stage of the disease.

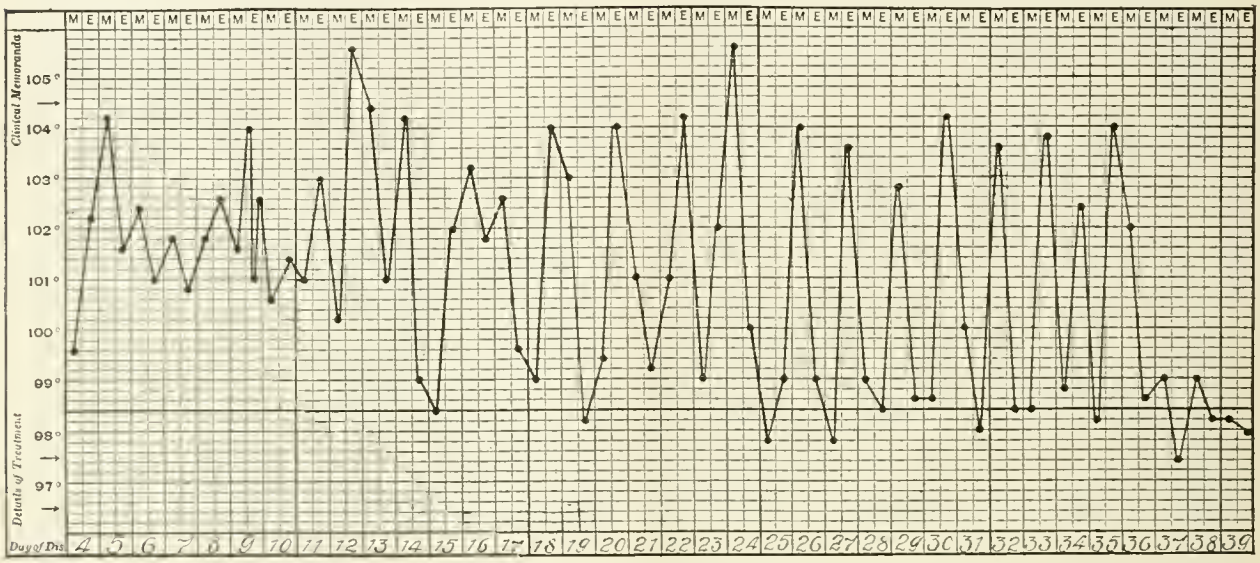
The patient was a boy of eleven years, Italian, who had been in good health up to four days before admission to St. Vincent's Hospital, in the service of Dr. Charles H. Lewis, at whose suggestion the case is reported. His past history is negative. Four days before admission, in December, 1907, he was taken suddenly with chills, loss of appetite, and vomiting, with pains in the back, arms, and legs. His symptoms increased in severity, and at the time of admission he was apparently in great distress, moaning, and complaining of great pain when any part of his body was moved, especially his neck and right arm. Both hands, wrists, and elbows were swollen, but not red; his tongue was coated, his lips were parched, and his pupils were equal and moderately dilated. There was no nystagmus or strabismus. His heart and lungs were normal and the abdomen was slightly retracted. There was no tache nor were there any petechiæ. Kernig's sign, owing to the great pain in his joints in general, was simulated but was not truly present.

On the following day his condition was changed. His neck was less stiff and painful. There remained, however, the pain in the elbows, wrists, and knees which had become more swollen and tender, there being a distinct effusion in the right wrist and knee. His urine was negative except for a trace of albumin, and the white blood count was 18,000 per c.m. Salicylates, gr. v. and sodium bicarbonate, gr. x, were given every four hours, and the joints were dressed with a 10 per cent. solution of guaiacol in glycerin.

During the first eleven days in the hospital the temperature varied from 101° to 104°. The joint symptoms improved rapidly, having about disappeared by the third or fourth day, and when the temperature reached normal on the twelfth day, no trace of effusion or pain was manifest and a diagnosis of rheumatism seemed warranted. The salicylates and external applications were stopped. On the next, the thirteenth day, the temperature rose again and here follows a period of twenty days with an intermittent temperature suggesting malaria or streptococcus infection. While distinctly intermittent it was not absolutely periodic, but simulated pretty closely an anticipating tertian form as the accompanying chart well shows. Moreover, the characteristic paroxysms of malaria were lacking, and examination of the blood showed no plasmodia. The white count at this time was 12,000. The patient was comfortable when the temperature was down, but complained chiefly of headache when it was up. Quinine, gr. iii, was given three times a day; it was increased to gr. v after four days and Fowler's solution, ♏ v, was added, but these apparently had not the slightest effect, and were stopped on the twentieth day of the disease.

The patient at this time was put upon a tonic and allowed to eat anything he chose, and sit up for two hours each day. No additional specific symptoms appeared, but it was evident that he was grad-

ually but progressively failing. At this late stage it was ascertained through the interpretations of an intelligent friend that a brother of the patient had died of some acute disease about a week prior to the admission of the patient, and on communicating with the physician in attendance it was learned that the probable cause of death was cerebrospinal meningitis. This fact led to a lumbar puncture. Slightly turpid fluid, 7 to 8 c.c. in amount, was drawn off, examined by the hospital pathologist, Dr. Mandel, and found to contain meningococci. Antimeningitis serum was supplied through the courtesy of Drs. Flexner and Jobeling of the Rockefeller Institute. Another puncture was made, and 7 to 8 c.c. of the fluid withdrawn and replaced by an equal amount of the antimeningitis serum. There was no perceptible change in the course of the temperature nor in the symptoms of the patient. The following day another puncture was made, again about 8 c.c. being withdrawn and this time replaced by 22 c.c. of the serum. The temperature which was then 104° fell to normal within twenty-four hours and remained there; the symptoms disappeared and the patient entered upon a rapid convalescence.



Temperature chart in the case of Cerebrospinal Meningitis treated with Antiserum

COLLAPSE AFTER INJECTION OF DIPHTHERIA ANTITOXIN.

By FIELDING LEWIS TAYLOR, M.A., M.D.,

NEW YORK.

On June 21, 1905, about 6 P. M., I saw Mr. J. G. C., aged thirty, publisher, who had been suffering since the previous evening from sore throat and chilly sensations. The right tonsil was somewhat swollen and there were scattered white patches on both tonsils which suggested follicular tonsillitis. There was some swelling of the lymph nodes on the right side. The temperature was 104° F., the pulse 90 to the minute. The patient gave a history of "heart-disease" in early childhood but nothing further was elicited. The heart was normal in size and there was a soft systolic murmur at the apex which was heard somewhat more feebly at the base also and not transmitted.

A culture was taken and three doses of phenacetin, gr. ijss, and salol, gr. x, at intervals of four hours were ordered, also a gargle of Dobell's solution and water. The following morning I received a report that the culture showed the presence of the Klebs-Loeffler bacillus, and about eleven o'clock called to inject antitoxin. The patient's temperature was then 101.5° F. and pulse 80. I administered 6,000 units of antitoxin, grade 6a, made by the Department of Health of this city. About ten minutes later the patient complained of tingling and numbness in the extremities which soon spread to the whole surface of the body. He began to cough and remarked that this was the first time that he had noticed any cough. He soon grew ghastly pale and then cyanotic and coughed up frothy fluid. His pulse was now very rapid and feeble. Suddenly he stopped breathing absolutely, became profoundly unconscious, stiffened out with a rattle in his throat, was covered with clammy sweat, and appeared to be dying. I at once did artificial respiration, when, after a few minutes, he took a long breath and began to breathe feebly, but remained comatose for half an hour. At the time of his collapse he had an involuntary discharge of feces. He was fully stimulated with hypodermic injections of strychnine and atropine. He remained rather cyanotic for an hour and a half while his finger tips and lips were very blue indeed.

At 3 P. M. his pulse was 130 and he complained of intense itching. At 6 P. M. his pulse was 90, temperature 99.6° F., and he was covered with diffuse erythema and giant urticaria. During his collapse many moist râles could be heard over his chest, which were later replaced by sibilant ones. At no time was he absolutely pulseless at the wrist.

The report of an examination of a specimen of urine obtained during the afternoon was as follows: Slightly cloudy, sp. gr. 1020, acid, distinct trace of albumin, no sugar, a few hyaline and epithelial casts, some renal epithelia, some whetstone crystals.

In the afternoons of the following three days he had some dyspnea with hoarseness and slight cyanosis, together with sibilant râles over the lungs and giant urticaria on the surface of the body. His urine became normal very soon, and he made an uneventful but rather slow convalescence.

The numbers of the phials containing the antitoxin were handed to the proper officers of the Department of Health, who reported that no trouble whatsoever had been encountered with other specimens from the same source. It is unnecessary to say that the antitoxin in use at present is more concentrated than that used three years ago. I report this case on account of the interest which is now being taken in this subject.

173 West Seventy-third Street.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, July 4, 1908.

THE FOURTH OF JULY.

THIS is the day we celebrate—the birthday of our country, the anniversary of a declaration of soul-inspiring principles by the patriot forefathers—a glorious day, the memory of which shall never fade. It is proper that such a day should be celebrated with joyousness and enthusiasm, and it should be especially celebrated by the young that its observance may inspire them to love of their country and reverence for the principles of liberty. But is it necessary in such a celebration to trample on the rights of others, to maim and slay peaceful citizens and innocent children, to kill sleep, and to make of the waking hours a purgatory of ear-splitting explosions? Is it necessary to burn up in one day as much money as was needed to carry on our war of independence for an entire year? Is it necessary to wound and kill in one day as many as were wounded and killed in six months during the war of the Revolution? Is that war to go on forever, and must we pay for our celebration each year by as many casualties as would be the result of a small battle?

In the June *Century*, Mrs. Isaac L. Rice contributes an article in protest against our barbarous manner of celebrating the Fourth, and contrasts it with the quiet and orderly observance of national holidays in the countries of Europe. She speaks of the fearful casualty list and the money waste of the celebration, but the point to which she draws especial attention is the intolerable noise and the evil effect of it upon the sick. She makes an earnest plea for a more rational observance of the day by the display of the flag, by the playing and singing of national music in the parks and other public places, by street parades with floats depicting important events in our national history, by outings in the country and the parks for the children, and in the evening by fireworks conducted by experienced men in open places.

In the *Housekeeper* for July, W. A. Frisbie relates the history of a "sane" celebration of the Fourth which did honor to Minneapolis where it was conceived and carried out. The day began with a flag-raising in the Parade, a new fifty-six acre park tract in the heart of the city, and this was followed by a general program of jollification. There were exhibitions of trained dogs, acrobats, jugglers, and the like, given continuously in different parts of the park so that all might have an opportunity to see; bombs were sent up which exploded in the air with little noise setting free numbers of grotesque figures which floated away in the wind, to the intense enjoyment of the youngsters. The inner boy also was not neglected—popcorn, peanuts, lemonade, all were free as air and much more filling. And with all there was not a firecracker, nor a toy-pistol, nor a giant torpedo. In a crowd estimated to number nearly 50,000 young and old, there was not a single casualty to mar a sane and safe celebration of Independence Day.

This was a good beginning along the lines suggested by Mrs. Rice, and we have sufficient faith in the good sense of our people, in the long run, to hope that as this manner of celebration becomes known it will be adopted generally. It is possible even that those among us who are on the sunny side of life may live long enough to wonder how it ever could have been that the people of this country used to celebrate the anniversary of an event of such importance to the welfare of the whole human family by maiming and killing each other and themselves.

HEREDITY AND THE EDUCATED CRIMINAL.

Two recent examples of men in public trust who have gone wrong, occurring at the extreme East and West of our country, call to mind the ultimate influence of heredity and early environment as a cause for what may be spoken of as a reversion to ancestral crime. In so far as one can secure the facts, both of these individuals rose from office boy and newsboy, respectively, to distinguished places in politics and the law. Each is said to have had a bad ancestral inheritance from criminal relatives, immediate or remote.

It is noticeable, and even remarkable, that such persons can overcome the very great obstacles to success found in bad early training, and can rise by sheer effort of the will to high spheres of usefulness. This fact indicates a great degree of histrionic ability on the one hand, and on the other a sort of pseudo-virtue, which is a counterfeit so neat and accurate as to defy detection for years, even to intimate acquaintances. Such men bear a most excellent reputation, and their true character may never be known in many instances, because they are fortunate enough to die before being compelled to show their real natures through an unavoidable chain of circumstances. Mr. Cleveland's reflection that many a self-made man is not worth the making is more true than pleasant. It is also true that many a self-made man was morally unfit before the real making began, and for an explanation of this type we are obliged to fall back upon antecedent history and such light as recent advances in psychology are able to provide for us.

One may say in truth that the correction of a tendency to faulty conduct never exists spontaneously in the criminally inclined, while in the morally balanced there is likely to be a retention of the deeper feelings for reverence and self-control which will delay utter and ultimate degradation. Lack of self-control must not be corrected merely; it must be over-corrected if moral deformity is to be prevented or cured; but seldom it is that congenital or acquired strength is sufficient to overcome a tendency to give way in those little things which are the start-

ing point of many a criminal career. The moral strength of the Puritans, however, lay just here. They allowed themselves absolutely no license, or what we are in these days pleased to speak of as "liberal-mindedness" and "breadth of view." For them all law was a definite, hard-and-fast, irrefragable element. There could be no slightest compromise even with the appearances of evil.

It is just possible that the responsibilities of great place are always too heavy for weak heredity. Temptations are too great and too constant. In the myopic eye all pleasures belong to the present, the future is too far off, too uncertain to enter a protest against wrongdoing. There is always a chance of escape, and no weakling will ever deny himself that one fond chance. Education in such case works a disadvantage. The educated unfortunate sins and hopes to be dealt with leniently on account of his superior intellect, or, barring that, trusts to his wits as a safeguard in furnishing a cloak for wrongdoing. Bad heredity weakens the entire physical and moral fabric. Acquired virtue, when put to the test, is only too apt to fail if there be no moral stamina derived through a line of strong-minded ancestors and added to by independent and conscious individual effort.

CHRONIC DIPHTHERIA.

Chronic bacilli carriers have received a great deal of attention lately in connection with the spread of typhoid fever. In the case of these bacilli the persons harboring them for a long time are usually quite free from symptoms of the infection, being naturally immune to the organism in question or having acquired such immunity by an attack of the disease. A somewhat different state of affairs exists in the case of chronic carriers of diphtheria bacilli. These individuals usually suffer from recurrent attacks of the disease and a good instance of such a condition is reported by Gabriel in the *Berliner klinische Wochenschrift* for June 8, 1908. The patient, a young woman, went through a severe attack of diphtheria, which was followed by a number of recurrences of throat symptoms, general malaise, and fever. Almost two years after the primary infection she was admitted to the hospital, and was kept in the general ward, although bacilli were isolated from the throat. An exacerbation occurred, and at the same time her neighbor in the ward and the attending nurse developed diphtheria; only then the patient was isolated. During a stay of seven months various therapeutic measures were tried, but proved useless, and the patient was discharged, still harboring the bacilli in the throat, only to return in a few days with a fresh attack of the disease. This stay ended as before with amelioration of symptoms and the discharge of the patient, though the seat of the disease was affected as little as in the previous stay. An examination of the blood by the Ehrlich Institute of Frankfort disclosed the interesting fact that the patient's serum possessed a high degree of immunity to the bacilli of diphtheria, over ten thousand immunity units being found. This explained the failure to obtain a positive blood culture, though the attempt to find the bacilli in the blood was repeatedly made. Passive immunization was not attempted in the face of the above finding.

This report is of interest from more than one point of view. First of all, of course, it discloses one more condition where even such an advanced therapeutic measure as specific immunization is of no avail; on the other hand, it once more brings to the foreground the question of dealing with such patients as are the source of great danger to the community through no fault of theirs. It has been proposed to compel chronic carriers of typhoid bacilli to undergo an operation for the removal of the gall-bladder, but in a case of chronic diphtheria like the above no similar treatment can be suggested. The hope lies in further study of the subject of immunity which may yet disclose an effective way to protect the community without unnecessary interference with the personal liberty of the unfortunate bacilli carrier.

A DEFENSE AND AN ESTIMATE OF VACCINE-THERAPY.

To anyone who has followed the voluminous literature of this subject it is plain that while the general principle of vaccine-therapy has proved quite useful, especially in chronic infections with the staphylococcus, the value of the various technical procedures originated by Wright in the application of the principle has been seriously questioned. It has been suggested that clinical symptoms are safe guides in the application of vaccine-therapy and in judging of the results obtained; that the opsonic index often fails to give uniform results at different times or in the hands of different observers; that, finally, opsonins are but one species of the protective substances in the blood and no such dependence is to be placed upon them alone as is done by Wright and his followers.

In a recent number of *The Practitioner* the originator of the method and those associated with him attempt to answer the above objections. In the introductory article Sir A. E. Wright states that a definite initial dose cannot be set as a standard for many reasons. The potency of the vaccine used can be only approximately standardized; the response to the dose is not uniform in the healthy and still less so in the infected subjects; the repetition of the immunizing doses may still further change the phenomena of response in each individual. On the other hand, clinical symptoms may be fallaciously interpreted, may not be complete enough to serve as a guiding principle, and may be so slow in changing in the case of chronic infections that untold harm may be done before the evidence of it appears to the observer. Fleming's article in the same issue is an answer to the criticism of the technique employed. He shows by many statistical tables that in the hands of Wright and his pupils the results of estimating the opsonic index, both in the healthy and in the sick, have been uniform enough to be safely depended upon in the application of the vaccine-therapy. Several other contributors testify in their articles to the partial success at least which was the reward of the careful application of Wright's principles of treatment.

The general reader, who is not himself applying

or testing the new treatment is at a loss to decide between the opposing camps of investigators. The editorial comment in the same number of *The Practitioner* is, perhaps, the best statement of the attitude to be adopted by him. "The method is a new and complex one, and, until its use has been more thoroughly explored, it should be carried out only under the guidance of an expert. . . . Whether an opsonic control of the injections will always be necessary still remains to be shown, but for a long time yet the exhibition of the vaccines should be preceded by a most careful bacteriological examination, and, if possible, the particular vaccine should be prepared for each individual patient. If these precautions are taken, there is little doubt that the opsonic method has a brilliant future before it; at present, however, it is certainly in the experimental stage, and should be so regarded."

The Effect of Tuberculin Upon Healthy Persons.

It is generally assumed that tuberculin acts as a poison to the healthy human organism as well as to one infected with tuberculosis, though the latter reacts to its influence much more readily and by greater intensity of symptoms. The exact relation of the healthy organism to the action of tuberculin has not, however, received much attention in the past, and a study of this subject made by Hamburger and reported by him in the *Münchener medizinische Wochenschrift* for June 9, 1908, is therefore of interest. This author says that the absence of any symptoms on injection of tuberculin is rare, not because the substance is toxic to the healthy as much as to the tuberculous, but because perfectly healthy individuals, quite free from foci of active or latent tuberculous infection, are but rarely met with. The well-known resistance of nursing infants to this toxin is explained by the absence of such foci in the great majority of such infants. Hamburger has observed several cases of adults who reacted as little as infants to such large amounts of tuberculin as 10 mg. for a dose repeated several times. He further injected from 10 to 100 mg. of tuberculin to each one of forty-three children, none of whom showed any constitutional reaction or rise of temperature after the injection. Of course, these doses of the toxin were used only after smaller doses had produced no reaction and the site of the puncture remained free from inflammatory phenomena. The explanation of this apparent lack of toxicity in a substance, usually assumed to be extremely toxic, is not very easy to find; Hamburger, however, used only the old tuberculin in his experiments, and thinks that the long steaming over a water bath to which this preparation is exposed may destroy the thermolabile toxins of the original product of bacterial metabolism. That the author was very sure of the lack of toxicity in the preparation used by him after the above facts were elicited is shown by his statement that one little girl of six years of age received an injection of 500 mg. of old tuberculin. His conclusions, however, proved to be correct; the child manifested no general phenomena of a reaction whatever.

Placental Transmission of Paratyphoid Infection.

The older pathologists thought that the infectious diseases were quite regularly transmitted from the mother to the child by the placental circulation. We know now that such transmission is a rare occurrence; not the disease is transmitted, but a predisposition to such a disease, as in the case of tuberculosis, or the child simply suffers from general malnutrition and maldevelopment because of the poverty of the mother's blood or the existence in it of the toxic products of disease. Isolated cases of placental transmission of disease, however, are frequently reported, and an article by Nauwerck and Flinzer in the *Münchener medizinische Wochenschrift* for June 9, 1908, adds paratyphoid fever to the list of infections that may thus pass from the mother to the unborn child. The infant in question died thirty-six hours after birth with symptoms of general melena, and the autopsy fully answered the clinical picture, blood having been found in the cerebral membranes, in the retina, in the internal organs, and especially in the stomach. A bacillus recovered from the blood was carefully tested bacteriologically and showed in its morphology, in the cultural reactions, and in virulence toward animals all the characteristics of the paratyphoid group. The mother gave a history of an acute disease a few weeks before labor occurred; her blood agglutinated the bacillus recovered from the child, as well as another laboratory strain of the paratyphoid organism. The probability of extrauterine infection was excluded by the advanced lesions found, though the infant lived only a day and a half, and the authors conclude, therefore, that theirs is the first reported case of a paratyphoid infection transmitted by the placental circulation.

Outbreak of Rabies.—The State Agricultural Commissioner of New York states that officials of his department have never known of such a serious outbreak of rabies as exists at present. Thirty towns in the State are under quarantine for the disease. In New York City the Health Commissioner has issued an order declaring that the running at large of dogs constitutes a public nuisance and menace to health, and calling on all owners to muzzle their dogs. Any dogs not muzzled or held in leash are to be destroyed by the inspectors or agents of the department. It is hoped that this muzzling order, which is to remain in effect until the end of October, will prove efficacious in stamping out the disease. In England, owing to the enforcement of such an order, the number of cases of this disease fell from 672 cases in 1895 to none in 1900.

Health Conditions in New York.—The lowest weekly death average in the city was recorded by the Board of Health for the week ending June 20, the rate being 13.45 per 1,000 as against 17.36 for the same week in 1907. The absolute decrease in the number of deaths was 332. The Borough of Manhattan showed the lowest rate, 12.99. The deaths in tenement houses numbered 255 as compared with 375 for last year. The Health Commissioner attributes this decrease to the better quality of food supplied in the tenement house district at present, yet the reports of the various relief societies indicate very clearly that there is great want and privation among this class because of the general hard times since last October. In a recent report of an investigation from a trustworthy source these conditions are said to be so bad as not to permit of exaggeration, and it is stated that both adults and children are undernourished as the result of very insufficient quantities and very in-

ferior qualities of food supplies. This condition has existed for some time, and yet the death rate for the first three weeks of June has been lower than ever before, and each week has had a lower rate than the preceding. A study of all the conditions in relation to fresh air, improved dwellings, diminished protein intake, etc., might, and might not give additional support to Chittenden's dietetic theories.

Plague in Trinidad.—Since the middle of June six new cases of plague have been reported, and active steps are being taken by the authorities in cleaning up the city and in destroying the rats. In Jamaica, also, the extermination of rats has been begun as a precautionary measure. The steamship *Caracas*, arriving in New York from Trinidad on June 21 was detained in quarantine because of the death of a fireman during the voyage, the cause of death not having been determined.

Medical Inspection of Chicago Schools.—The medical inspectors of schools of Chicago recently examined 4,783 pupils and excluded 241 because of contagious diseases. The chief causes of exclusion were as follows: measles, 20; tonsillitis, 42; chickenpox, 19; whooping cough, 15; diphtheria, 9, and mumps, 6. A total of 212 vaccinations were performed on school children, and 25 cultures were made for bacterial examination. Physical examinations made by the school medical inspectors in the schools during the week ended June 20 numbered 1,843. Of these 1,041 were of pupils who needed medical or surgical treatment. The parents were notified of the conditions found and were advised to consult the family physician.

Doctors Receive Degrees.—Colonel William C. Gorgas, the recently elected president of the American Medical Association, and chief sanitary officer of the Isthmian Canal Zone, received the degree of Master of Science from Harvard University, and Dr. Graham Lusk, Professor of Physiology in the New York University and Bellevue Medical College, the degree of Doctor of Science from Yale, at the commencement exercises of these universities held on June 24. Dr. Charles E. Nammack of New York received the degree of Doctor of Laws at the annual commencement of Fordham University on June 17.

Street Car Accidents.—With the bringing into service of the open cars on the street railway lines in New York, the number of accidents has very greatly increased. The report of the Public Service Commission states that during the month of May there were 5,152 accidents, against 4,707 in April. A considerable part of this increase is attributed to mishaps in alighting from and boarding the cars. In May 627 persons were injured as they got on the cars, in April only 562; and in May 772 persons were hurt in getting off cars, in April only 544.

Memorial to Dr. Reed.—In a recent issue of *Janus*, an historical medical journal published in Holland, Dr. John C. Hemmeter of Baltimore urges that the names of Dr. Lazear and Dr. Carroll, who were also members of the Yellow Fever Commission, be included in the memorial monument to be erected to Dr. Walter Reed in Washington.

Surgery in Partial Vacuum.—Dr. Sauerbruch of the University of Marburg recently demonstrated, before the staff of the Rockefeller Institute, his method of performing chest operations in a glass operating cage in which the normal atmospheric pressure had been reduced, so as to prevent collapse of the lungs.

Hospital Struck by Lightning.—The Newark Tuberculosis Hospital on the top of Mt. Caldwell, at Verona, N. J., was struck by lightning on June 24, causing a small panic among the inmates. As the building is fireproof no serious harm resulted.

Raise Entrance Requirements.—Jefferson Medical College, the Medico-Chirurgical College, Hahnemann Medical College, the Woman's Medical College of Pennsylvania, and Temple University, have notified the Pennsylvania State Medical Council that hereafter only such students as have pursued at least a full four years academic or high school course shall be eligible for the medical course. It is stated also that the Western University of Pennsylvania at Pittsburg will shortly or in the next year adopt a similar minimum entrance requirement. The University of Pennsylvania has already made announcement that it will receive in its medical department only students who have passed at least one year of the college course.

Larger Bellevue Opposed.—A report just made by the State Charities Aid Association, concerning the hospital needs of New York City now and up to 1920, urges the establishment of emergency relief stations at convenient distances from existing hospitals. Five such stations are now needed and by 1920 this number will be increased to fourteen. Such stations are to have eight beds each. The report states that 540 additional beds are needed in the city hospitals at this time, and that by 1920 there will be a demand for 2,772. These emergency stations, it is suggested, can be eventually replaced by small hospitals. The committee believes that it would be advisable to change the plans for the new Bellevue Hospital so as to reduce the number of beds from 2,000 to 1,600, with a view to expending the money thus saved on the erection of other hospitals elsewhere. It is recommended that steps be taken immediately to procure hospital sites in outlying districts while land can be obtained at comparatively reasonable rates. The committee urges also the establishment of two general hospitals on Blackwell's Island, one at each end, each to have not more than 1,500 beds.

The Gibbs Prize.—The New York Academy of Medicine announces that essays in competition for the Edward N. Gibbs Memorial Prize will be received up to October 1, 1909. The subject is to be "The Etiology, Pathology, and Treatment of the Diseases of the Kidney," the three parts not necessarily to be treated with equal detail. In order to obtain the prize an essay must show originality, and new discovery or fruitful research will be considered the standard of merit. Manuscripts must be in English, typewritten, designated by a motto or device, and accompanied by a sealed envelope bearing the same motto or device, which shall contain the name of the author. The amount of the prize is $1,000; but the Academy reserves the right not to award the prize if no essay shall be found worthy. Essays are to be sent to the Committee of the New York Academy of Medicine on the Edward N. Gibbs Memorial Prize. The successful essay becomes the property of the Academy.

The Right to Resign from a Medical Society.—Dr. Charles J. Mooney, who claimed that he had been unjustly treated by the officers of the Medical Society of the County of New York, some time ago tendered his resignation as a member of that organization. In his letter to the secretary he gave as the reason for his resignation that he could not "conscientiously remain in an organization whose unfair methods were demonstrated in

the proceedings of last year." The comitia minora replied through the secretary that it "declined to receive a document couched in language offensive to the society." Dr. Mooney then applied to the court and Justice Blanchard has now decided that he was within his rights in using the language he did, and that the society must accept his resignation.

Dr. Francis Carter Wood, Professor of Clinical Pathology in the College of Physicians and Surgeons of New York, and president of the Alumni Association of the Ohio State University, delivered an address on the relation of the State university to medical education at a meeting of the alumni of that University on June 23.

Dr. William Osler, regius professor of medicine at Oxford University, has consented to contest for the lord rectorship of the university of Edinburgh in November as a nonparty candidate. He is the first physician ever nominated for the office.

Dr. Carl Beck of New York has received the decoration of the Order of the North Star from the King of Sweden.

Changes in Faculty of the Northwestern University.—Dr. Frederick Menge has been appointed professor of Rhinology and Laryngology and made head of that department in place of Dr. Wm. E. Casselberry, who has resigned that position and has been made professor emeritus of Rhinology. Dr. J. M. Neff has been made Associate Professor of Surgery, and Dr. Frederic A. Besley, Dr. H. M. Richter, and Allen B. Kanavel, Assistant Professors of Surgery. Drs. W. R. Cubbins and Frank E. Pierce have been appointed assistants in surgery, and Drs. Charles Matter, John C. Hollister, F. G. Dyas, and Wm. C. Danforth, instructors in surgery. Drs. George B. Dyche, Paul Chester, Charles A. Elliott, and A. Davis have been promoted to the positions of Assistant Professors in Medicine. Dr. W. H. Buhlig has been appointed Assistant Professor of Clinical Pathology; Dr. Joseph Brenneman as Assistant Clinical Professor of Pediatrics; Dr. Robert T. Gilmore, Assistant Professor of Gynecology; Dr. Prentiss of Harvard University, Assistant Professor of Anatomy, and Dr. S. Walter Ransom, Associate in Anatomy.

Courses in Pediatrics and Infant Feeding.—Prof. Schlossmann has arranged for a number of post-graduate courses in the Nourishment and Diseases of Infants at the Infants' Hospital at Düsseldorf, Germany. The courses will last for two weeks each.

Medical Club of Philadelphia.—Dr. William C. Gorgas, President-elect of the American Medical Association, Dr. William L. Estes, President of the Medical Society of the State of Pennsylvania, Dr. Albert M. Eaton, President of the Philadelphia County Medical Society, Dr. W. A. Evans, Health Commissioner of Chicago, and Dr. Walter Wyman, Surgeon-General of the United States Public Health and Marine-Hospital Service, were the guests of honor at a reception given by the Medical Club of Philadelphia on June 12.

Lake Keuka Medical and Surgical Association.—The ninth annual meeting of this society will be held at Grove Springs, Lake Keuka, N. Y., on July 9 and 10, 1908, under the presidency of Dr. Lewis Wheeler Rose of Rochester. The society includes in its membership physicians from Allegany, Schuyler, Chemung, Livingston, Tioga, Monroe, Wayne, Ontario, Wyoming, Steuben, and Yates counties. An attractive program of twenty titles is offered. The secretary is Dr. H. B. Nichols of Pulteney. Grove Springs is reached by steamer from Hammondsport via the Erie and Lackawanna, and from Penn Yan via the N. Y. C. and N. C. railroads. It is also accessible by auto from these points.

XIV International Congress in Hygiene and Demography.—The Secretary General reports that with the issuing of the four volumes covering its proceedings the work of the Congress for 1907 is completed. The last two volumes will be forwarded to members of the Congress, and the entire set will be published by Hirschwald of Berlin and may be obtained through booksellers for fifty marks for the set, or by single volumes.

The Fifth Pan-American Medical Congress will be held in Guatemala City, August 5 to 10, 1908. From New York, Guatemala may be conveniently reached by train to New Orleans, thence by boat to Puerto Barrios on the Gulf, and again by train to Guatemala City. The trip takes seven days, and the cost, exclusive of sleeper and meals, is $56. The capital of Guatemala is situated on a plateau, one mile above sea level. During August there is usually no rain, and the heat is said to be less than in our Southern States. Information may be obtained from the secretary, Dr. Ramon Guiteras, 75 West Fifty-fifth street, New York.

Association des Médecins de Langue Française de l'Amérique du Nord.—The IV Congress of the Association will be held in Quebec, on July 20 to 22, 1908. The four sections of medicine, surgery, hygiene, and dental surgery will be covered, and particular stress will be laid upon instruction in hygiene, infection of the bile ducts, and renal tuberculosis. Ample provision is being made by the committees for those who wish to attend, and reduced railroad fares are offered.

The VIII International Congress of Hydrology, Climatology, Geology, and Therapy by Physical Agents will be held at Algiers, April 4 to 10, 1909.

Chicago Medical Society.—After a closely contested election, balloting resulted in the election of the following officers for the ensuing year: *President,* Dr. Alfred C. Cotton; *Secretary,* Dr. Merlin Z. Albro; *Councilors at Large,* Drs. Elmer E. Henderson, Henry B. Favill, J. Chase Stubbs, C. Hubart Lovewell, and Geo. H. Weaver; and *Alternate Councilors at Large,* Drs. William M. Harsha, Clark A. Buswell, Albert E. Mowry, Henry W. Cheney, and Paul F. Morf.

Chicago Surgical Society.—At the annual meeting of this Society, recently held, the following officers were elected for the ensuing year: *President,* Dr. A. E. Halstead; *Vice-President,* Dr. Arthur Dean Bevan; *Secretary,* Dr. Frederick A. Besley; *Treasurer,* Dr. John C. Hollister.

The Des Moines Valley (Iowa) Medical Association, at its thirty-seventh annual convention at Ottumwa, Ia., on June 18, elected the following officers: *President,* L. A. Rogers of Oskaloosa; *First Vice-President,* F. T. Stevens of Mount Pleasant; *Second Vice-President,* C. B. Powell of Albia; *Secretary-Treasurer,* Fred Bowles of Ottumwa.

The Aroostook (Me.) Medical Association held its annual meeting on June 16, at which the following officers were elected: Harry L. Putnam, Houlton, *President;* S. W. Boone, Presque Isle, *Vice-President;* F. H. Jackson, Houlton, *Secretary;* W. E. Sincock, Caribou, *Treasurer;* Harry L. Putnam

and S. W. Boone, *Delegates* to Maine Medical Association.

The Woonsocket District (R. I.) Medical Association.—At the annual meeting of this Society held on June 18, the following officers were elected: *President,* Dr. Elisha D. Clarke; *Vice-President,* Dr. John J. Baxter; *Treasurer,* Dr. George R. Smith; *Secretary,* Dr. William F. Barry; *Counsellor,* Dr. William C. Monroe; *Delegate to State Medical Society,* Dr. George R. Smith; *Censors,* Drs. John T. Roswell, Robert G. Reed, J. Edgar Tanguay.

Association of Medical Officers of the Army and Navy of the Confederacy.—At the annual meeting of this society, held in Birmingham, Alabama, on June 9 and 10, the following officers were elected: *President,* Dr. J. C. Abernathy, Birmingham; *Vice-Presidents,* Dr. William F. Beard, Shelbyville, Ky., Dr. E. N. D. Newton, Athens, Ga., and Dr. George M. Burgett, Lebron City, Tenn.; *Secretary,* Dr. A. A. Lyon, Nashville, Tenn.

The National Association for the Study and Prevention of Tuberculosis held its annual meeting in Chicago on June 5 and 6, and elected the following officers for the ensuing year: *President,* Dr. Vincent Y. Bowditch, Boston; *Honorary Vice-Presidents,* the President of the United States, Hon. Grover Cleveland, and Dr. William Osler, Oxford, England; *Vice-Presidents,* Homer Folks, New York City, and Dr. Charles L. Minor, Asheville, N. C.; *Treasurer,* Brig.-Gen. George M. Sternberg, Medical Corps, U. S. Army, retired, Washington, D. C.; *Secretary,* Dr. Henry Jacobs, Baltimore; *Executive Secretary,* Livingston Farrand, New York City; and *Directors,* Drs. John N. Hurty, Indianapolis; S. Adolphus Knopf, New York City; Victor C. Vaughan, Ann Arbor, Mich.; Edward R. Baldwin, Saranac Lake, N. Y.; Rudolph Matas, New Orleans, and Messrs. James J. Hill, St. Paul.; Frederick Redfield Proctor, Proctor, Vt.; J. B. Bixby, St. Louis; C. B. Boothe, Los Angeles, and A. B. Cummins, Governor of Iowa.

Essex South District Medical Society (Mass.).—The annual meeting was held on May 19. Dr. William G. Mumford delivered an address on the "Principles of Cerebral Decompression." The following officers were elected: *President,* Dr. S. P. E. Cooke, Gloucester; *Vice-President,* Dr. F. W. Baldwin, Danvers; *Secretary,* Dr. G. K. Blair, Salem; *Treasurer,* Dr. G. Z. Goodell, Salem; *Librarian,* Dr. C. M. Cobb, Lynn.

The Hampshire District Medical Society held its annual meeting at Springfield, Mass., on May 14, and elected the following officers: *President,* W. W. Miner of Ware; *Vice-President,* F. H. Smith of Hadley; *Secretary,* A. G. Minshall of Northampton; *Treasurer,* A. H. Hoadley of Northampton; *Librarian,* E. W. Brown of Northampton; *Chairman of the Board of Censors,* A. M. Belden of Northampton.

The South Bristol (Mass.) Medical Society at its annual meeting, held on May 14, elected the following officers: *President,* Dr. William T. Learned; *Vice-President,* Dr. A. A. Mandell of New Bedford; *Secretary and Treasurer,* Dr. A. J. Abbe; *Councillors,* Drs. C. A. Bonney, New Bedford, A. W. Buck, W. A. Dolan, J. H. Gifford, and C. D. Hough and C. A. Pratt of New Bedford; *Censors,* Drs. A. I. Connell, W. A. Dolan, H. G. Wilbur, and J. C. Pothier and A. P. Webb of New Bedford; *Commissioner on Trials,* Dr G. L. Richards.

The New Hampshire Medical Society held its one hundred and seventeenth annual meeting in Concord on May 15, and elected the following officers: *President,* Dr. John M. Gile, Hanover; *Vice-President,* Dr. Frank Blaisdell, Goffstown; *Councillors,* Belknap county, Dr. A. H. Harriman, Laconia; Grafton county, Dr. M. S. Woodman, West Lebanon; *Trustee for three years,* Dr. W. T. Smith, Hanover; *Member Board of Medical Examiners,* Dr. J. F. Robinson, Manchester; *Alternate,* Dr. G. C. Wilkins, Manchester; *Delegate to Dartmouth Medical College for two years,* Dr. A. C. Heffener, Portsmouth; *Anniversary Chairman,* Dr. H. N. Kingsford, Hanover.

The Norwich (Conn.) Medical Association at its annual meeting, on May 4, elected the following officers: *President,* Dr. W. Tyler Browne; *Vice-President,* Dr. N. P. Smith; *Secretary,* Dr. L. F. LaPierre.

The West Tennessee Medical Association on May 22 closed its annual meeting at Jackson, Tenn., with a symposium on tuberculosis. The following officers were elected by the society for the coming year: *President,* F. A. Smythe, Memphis; *Vice-President,* J. R. Nelson, Eurekaton; *Secretary,* A. A. McSwain, Paris.

Obituary Notes.—Dr. Joseph M. Finnell of St. Paul, Minn., died on June 13, of apoplexy, at the age of 48 years. He was graduated from the medical department of New York University in 1887, and had served as secretary of the Coroner's department of St. Paul for a number of years.

Dr. Frederick Lacy Wheeler of Minneapolis, Minn., died on June 14, at his home. He was a graduate of the medical department of the University of Minnesota in the class of 1904.

Dr. Daniel E. Millerick of Stoneham, Mass., died on June 18, at the age of 52 years. Dr. Millerick was graduated from the Harvard Medical School in 1881.

Dr. John Gilman McAllister of Lawrence, Mass., died on June 20, after a long illness, at the age of 67 years. He was graduated from the College of Physicians and Surgeons of New York in 1863, and served in the army as assistant surgeon until the close of the war.

Dr. Michael J. Neville of Brooklyn, N. Y., died on June 22, at the age of 37 years. Dr. Neville was a graduate of Queen's College, Canada, in the class of 1893, and was consulting surgeon of St. Catherine's Hospital, Brooklyn.

Brig.-Gen. Albert Hartsuff, a retired army surgeon, died on June 22 in Detroit, Mich., at the age of 70 years. Graduated from the Castleton Medical College, Vermont, he entered the service on the outbreak of the Civil War as an assistant surgeon, and was rapidly promoted, distinguishing himself during a yellow fever epidemic in New Orleans in 1866. In 1904 he was advanced to the rank of brigadier-general retired.

Dr. George F. Heath of Monroe, Mich., a graduate of the Medical Department of the University of Michigan, died on June 16, at the age of fifty years.

Child Suicide in Germany.—It is estimated that the number of cases of suicide among German school children between the years 1880 and 1903 exceeded 1,000. There were more cases of suicide among boys, in the proportion of four boys to one girl, under 15 years old, and forty-eight to one above this age. The causes are attributed in 336 cases to fear of punishment, in 70 to mental disorders, and in 68 to intemperance. Other causes were disappointments in love, despair induced by the premature reading of Nietzsche and Schopenhauer, and religious doubts.

MEDICINE AND SCIENCE AT THE FRANCO-BRITISH EXHIBITION—INGLEBY LECTURES ON MYOMA OF THE UTERUS—OLIVER-SHARPEY LECTURES ON OUR KNOWLEDGE OF THE ADRENALS—OBITUARY.

LONDON, June 12, 1908.

You have no doubt heard a great deal about the Franco-British Exhibition, which, although it is not yet finished, is attracting immense numbers of visitors. It is on a scale exceeding that of any previous international exhibition. Among its numerous attractions there is the Hall of Science, a building containing floor space of about 14,000 square feet and on which I hear the committee has expended £7,000. It is not in a prominent position and may easily be missed, but will afford much pleasure to any one who visits it. Electricity, magnetism, chemistry, astronomy, meteorology, have their separate divisions and the exhibits have been arranged by masters in the several sciences. Space forbids me to enter on a description of these marvels, but I must give you a few notes respecting the medical department. The Liverpool School of Tropical Medicine, always to the fore, has an excellent exhibit illustrating the work it has been doing. The tsetse fly, the enlarged glands of sleeping sickness, photographs of suffering natives, etc., are shown. So is a portrait of Major Ronald Ross and his original manuscript proving the transmission of malaria by mosquitos. Here, too, are a number of specimens connected with elephantiasis and representatives of the species of rats which carry plague. The London Tropical School has also an exhibit showing the progress of discovery in this department. The Royal Microscopical Society shows microscopes arranged in chronological order to illustrate the successive improvements in this means of investigating, beginning with a copy of Leeuwenhoek's (1675) and Masschenbroek's (1702). In the anthropological section are numerous measuring and weighing instruments.

In another part of the grounds there is an exhibit of a medical kind. This is in the Irish Village, which is attracting great attention. In the Village Hall there is a reproduction on a small scale of the Tuberculosis Exhibition which has been touring in Ireland in order to bring home to the people the ravages of this disease, and the way in which they may restrain it. There is a pathological division with specimens of human lungs in various stages of phthisis; and a veterinary division with specimens from animals. A section is devoted to appliances—sputum flasks, spittoons, milk sterilizers, etc. Then there are maps, diagrams, and literature devoted to the statistics of tuberculosis, and "contrast bedrooms," illustrating the conditions which encourage and discourage the development of phthisis. The pamphlets distributed include lectures by leading authorities and ample instruction on ventilation, milk supply, cleanliness, and so forth. Short expositions are also delivered throughout the day on all points connected with the cause and prevention of the disease—a valuable object lesson being thus enforced.

The Ingleby lectures at the University of Birmingham were delivered last month by Dr. Christopher Martin. He is surgeon to the Birmingham and Midland Hospital for Women, and took for his subject Myoma of the Uterus, on which his experience enables him to teach with considerable authority. The two lectures of the series were devoted respectively to the dangers and treatment of the disease. He said that the more he saw of it and the more he followed up his cases, the more he was impressed with its risks and grave complications. The commonest of these is hemorrhage, and though it is rare for a patient to bleed to death, chronic anemia and extreme weakness result and are responsible for brown atrophy and fatty degeneration of the heart in many neglected cases. It is also the main factor in thrombosis and phlebitis. Pain is uncertain—mostly discomfort is complained of—but when the ovaries and tubes are inflamed and adherent the pain is severe. Pressure symptoms are numerous and vary with the organ pressed upon. They frequently call for surgical treatment. Lesions of the appendages are found in about a third of all cases of myoma submitted to operations. In many cases probably the myoma is responsible for these lesions, and in most cases endometritis to some extent is present. The hemorrhages and anemia affect the heart, and Dr. Martin quoted the Ingleby lecturer of last year (Dr. Thomas Wilson) as having carefully studied the relation of myoma to cardiac disease with a result that over 40 per cent. of patients with severe myoma have some form of cardiac insufficiency. Ergot would in them be contraindicated as increasing peripheral resistance by contracting the arterioles. Rest would be needed prior to operation, after which improvement in the heart symptoms usually occurs. The lecturer next considered the degenerative changes to which myomata are so peculiarly liable. He divided them into three groups: (1) Nonmalignant degeneration *without necrosis*, occurring in about 14 per cent. of the cases; (2) nonmalignant, *with necrosis*, occurring in about 4 per cent., and (3) malignant degenerations and complications, also in about 4 per cent. Each of these groups was analyzed and its significance pointed out, and then the relation of myoma to pregnancy was considered. It was seen that sterility appeared nearly four times as often in myomatous patients as in those not afflicted with myoma. This, Dr. Martin, considers fortunate, as the occurrence of pregnancy adds greatly to the dangers of myoma. Some have supposed that the sterile state in some mysterious way may give rise to myoma, but the lecturer held that such theorists "put the cart before the horse." Some patients with moderately large fibroids pass through pregnancy and labor safely. But if the tumor be submucous or interstitial, abortion generally occurs by the fourth month—the best thing for the patient. Sometimes abortion has to be induced. However it occurs, retention of placental tissue and alarming hemorrhage is apt to follow, and in a submucous case there is the danger that the tumor may necrose and be a source of sepsis. A large fibroid may mechanically interfere with the development of the pregnancy and even necessitate surgical interference. It may also be impacted so as to obstruct or even prevent delivery, or interfere with the after contraction, and so cause retention of placenta, or itself be so bruised and injured as to lead to its necrosis and fatal sepsis. The danger to the patient is great in these cases, and the mortality high, for surgery is often postponed until too late. The lecturer summarized the risks which a woman with a fibroid runs as follows: (1) More than half these patients suffer from severe hemorrhage and chronic anemia; (2) many develop cardiac disease, phlebitis, thrombosis, and embolism; (3) others have retention, cystitis, pyelitis, hydronephrosis; (4) in about a third of the cases the ovaries and tubes become diseased; (5) in about a fifth, degeneration occurs, ending in nearly 5 per cent. in necrosis of the growth, and in 4 per cent. sarcoma, and a further 4 per cent. cancer; (6) half the patients are sterile, but should pregnancy occur the dangers increase as gestation progresses.

The question of a natural cure was then considered, and it was admitted that such an event may take place in three ways: (1) A submucous fibroid may necrose and slough away or be extruded through the cervix as a polyp and drop off. The risks of such a case were pronounced greater than those of the most formidable modern operation. (2) The myoma may participate in the involution of the puerperium and disappear. This is not to be reckoned on, for in many cases the opposite occurs—instead of shrinking the tumor is more likely to take on more active growth; (3) it may atrophy at the menopause. This was once thought to be the usual result, and a woman was told that her trouble would cease at that time. But sad experience shows that these hopes are illusory. At this period the dangers increase, as degenerations are more apt to supervene. Noble, in an analysis of 4,880 cases, declared he was not acquainted with a single case of such disappearance at or after the menopause. Dr. Martin's conclusion from these circumstances is that, realizing the manifold danger of myomata—the pressure, cardiac and renal complications, risks of degenerations, necrosis and malignant disease—and, on the other hand, the safety and the certainty of cure by surgery—it is not justifiable to advise a patient with a troublesome fibroid to wait for the menopause.

The present condition of our knowledge regarding the functions of the suprarenal capsules was chosen as the subject of the Oliver-Sharpey lectures at the Royal College of Physicians. Professor Schäfer was the lecturer, and he remarked that the congeniality of the position was enhanced to him by the fact that Sharpey was his honored master, and Oliver, who founded the lectureship, was his colleague in the research on the capsules, which led him to select the subject of his lectures. In his first lecture he traced the history of our knowledge, such as we have, of the functions of these bodies, down to the autumn of 1893, when Dr. Oliver called upon him to discuss certain results which he had obtained from extracts of animal tissues given by the mouth. At this visit these two pupils of Sharpey agreed to devote the winter to a thorough investigation of the physiological effects of such extracts.

They soon found that some of these extracts were inert, but that the suprarenal capsules and, to a less extent, the pituitary body, yield to glycerin and to water and to saline

solutions, principles having an extraordinary effect upon the tone of the heart and arteries—transcending the effect of any known drug. In March, 1904, they reported their results to the Physiological Society and thus opened a new chapter in this interesting history, for others set to work to isolate the active principle of the extract and determine its relationship. Success was so far obtained as to show that this principle is of relatively simple constitution, insoluble in alcohol, dialyzable, and not destroyed by acids or the gastric juice. Abel of the Johns Hopkins University was one of those who continued the investigation and crystallized compounds from the extract. Thus practitioners became possessed of a powerful drug—epinephrin or adrenalin or perinephrin. Other names have been proposed, but the one most in use is adrenalin, but this seems to have been registered by a commercial firm, and Professor Schäfer would therefore prefer to call it adrenin. How it is formed in the body remains to be discovered.

With regard to its effects, the first point established was the remarkable rise in blood pressure produced by a mere trace if injected, due to two causes: (1) contraction of the arterioles; (2) increased force and rate of the heart's beat. Sometimes, instead of augmentation, it produced inhibition. Then, it was held, two antagonistic influences were at work, constriction of arterioles, tending to raise the blood pressure, and cardiac inhibition, tending to lower it. The former was always the stronger, and if both vagi were cut, or a dose of atropine given, inhibition was prevented.

With regard to the clinical uses of adrenin, the lecturer mentioned Miller's account in the *Journal of the American Medical Association* for May, 1907. As not much has been added during the year that has elapsed since the article, I think I may as well pass over the subject, especially as the MEDICAL RECORD will furnish its readers with notices of all that is important. It is, therefore, only necessary to add that those desirous of studying the *modus operandi* will find much to think over in Professor Schäfer's statement of the physiological facts that have been established by himself, Oliver and others.

Inspector-General Andrew Maclean died on Monday at the ripe old age of 96. He graduated at Edinburgh, M.D., 1833, having taken the license of the Edinburgh College of Surgeons in 1831. He was formerly in the army medical service and retired as Department Inspector after serving as surgeon to the Garrison Hospital at Chatham and to the Royal Military College, Sandhurst. One of his sons is Kaid Sir Harry Maclean, of whose career in Morocco you must have heard, and of whom his father was very proud. Another son is following his father in the medical corps, and a third was until recently British Consul at Casabianca.

Another aged practitioner, Dr. Prior Purvis, died on the 29th of May, in his 96th year. He qualified in 1834, L.S.A., and next year took M.R.C.S. The establishment of the London University opened the way for degrees, and he was among the first candidates, taking the M.B. at the first examination (1839) and followed on to M.D. (1842). He was for many years surgeon to the Royal Kent Dispensary, treasurer of the West Kent Medico-Clinical Society, and closely connected with many other institutions. The annual "Purvis Oration" was established in his honor and has been delivered by some of the foremost of our medical leaders.

Dr. John Gill died on the 5th inst. in his 86th year. He qualified in 1875 and was for some time physician to to Margaret Infirmary for Consumption, and to the Royal Asylum of St. Anne's Society. He then became physician to the London Medical Mission. Besides a few contributions to the journals, he translated "Olshausen's Commentary" from the German and Bovet's "Life of Zinzendorf" from the French.

OUR PARIS LETTER.

(From Our Special Correspondent.)

DEATH OF CHARLES CHAMBERLAND—DEATH OF PROFESSOR RICHE—THIRTY-FOUR GAUZE SPONGES IN THE ABDOMEN—LENGTH OF STAY IN BED AFTER ABDOMINAL OPERATIONS.

PARIS, May 30, 1908.

CHARLES CHAMBERLAND, Assistant Director of the Pasteur Institute, died a short time ago at the age of fifty-seven. In his person we have lost one of the best of the fellow-workers of Pasteur, who helped that master to establish a new and rigorous technique, and then accomplish the great series of achievements that have made the name of Pasteur famous. The great discoveries in which Chamberland had share are as follows: The etiology and the prophylaxis of anthrax, vaccination against swine erysipelas, and the preventive treatment of rabies. He demonstrated that in the technique of practical surgery the bacteria of the air may be safely neglected, and that the careful sterilization of the hands, the instruments, and the dressings is sufficient to protect the patient against infection. He showed that the temperature of 100° C. is not sufficient to kill certain spores, that remain inactive so long as the medium is acid, but begin to multiply as soon as the reaction is changed to alkaline. To kill such spores the temperature must be raised to 115° C. and kept at that point for twenty minutes, and to accomplish this Chamberland devised an autoclave which is now universally used for the sterilization of various utensils, and has thus become indispensable in bacteriological laboratories, in the operating rooms, and in central disinfecting stations. He, too, has given us the indispensable filter provided with the porcelain candle: he spent much time in studying how the porous substances retain various particles from liquids suspending them, and has thus reached the conclusion that porcelain is best fitted for this purpose. With this new and perfect filter he was enabled to continue further researches in the field of bacterial excitants of disease; the filter at the same time proved useful in the purification of various beverages. In general, his work as a hygienist was very important, and in recognition of it he was elected member of the Academy of Medicine. With his death French science has lost a talented worker, practical and scientific in his accomplishments: his name will ever be remembered in connection with the great epoch he represented.

The Academy of Medicine has just lost one of its oldest ex-presidents, in the person of Professor Riche. For the last twenty-five years he has filled the position of Professor of Mineral Chemistry in the Paris School of Pharmacy. He was an extremely able teacher, and a facile and elegant lecturer, who could make the most difficult experiments and demonstrations comprehensible to the students. In addition to his work at the School of Pharmacy he was also the Director of Assay at the Mint. Professor Riche was especially interested in the study of metallic alloys and succeeded in discovering a combination of copper and of tin which proved to be a malleable alloy easily hammered into sheets. From his pen are two works on chemistry which give a *resumé* of the subject as taught by him at the School of Pharmacy. He was President of the Academy of Medicine in 1902, and in that year, in the presence of the President of the Republic, he opened for scientific sessions the new hall of the academy.

Dr. Richelot, speaking for Dr. Henry Loze of Berck, reported to the Surgical Society a curious case of a foreign body in the abdomen. A surgeon, after an operation for appendicitis, was compelled to leave his patient in the care of an assistant. He instructed the latter to introduce a bit of gauze drainage similar to the piece of gauze used at the operation, at each subsequent dressing. This order was dutifully obeyed by the assistant, who introduced a new piece of gauze at each dressing without ever removing the pieces previously introduced. In this way in about a month he had succeeded in putting some thirty-odd pieces of gauze into the abdomen of the woman patient. The strangest thing in the case is that the skin closed over the wound and the contained dressings never gave any trouble for the three years following the operation. Then, all of a sudden, there appeared intense pain all over the abdomen, accompanied by vomiting, nausea, meteorism, and the facies of acute peritonitis. At first an intestinal obstruction was diagnosed, but the patient was in such a feeble condition that it was decided to defer an operation. The general condition of the patient improved in the following days, and at the same time a point of fluctuation appeared at the site of the old cicatrix. An incision was made over this point, and by means of a sound a bit of gauze dressing was removed, which still retained the shape of the intestinal coils. After this the patient continued to expel pieces of gauze dressings by the wound, thus bringing to light thirty-four old dressings. As a consequence of the long illness and the constant employment of morphine made necessary by the pain, the patient became very cachectic and weak, and was now in a precarious condition, suffering from a fecal fistula at the site of the wound made for the removal of the gauze. Of course, the point of interest in this case is the large number of the dressings which the patient carried in her abdomen without symptoms for such a long period of time.

An interesting discussion took place after the report of this case as to the duration of the stay in bed advisable after abdominal operations. M. Jean-Louis Faure thought that, as rapid healing of the abdominal incisions is now the rule, there is no reason why patients should be kept in bed after a modern operation as long as in the past. In his opinion, the general health of the patient was very

favorably influenced by as short a stay in bed as was possible. In fact, for a person feeling well the stay in bed is a most unpleasant and uncomfortable restraint. His appetite becomes impaired, his bowels become sluggish, and when he is allowed to leave his bed he finds himself unable to keep on his feet, many days passing before he regains his former strength. The speaker said that for the last ten years he had allowed his patients, both in hospital and private practice, to leave the bed twelve days after a laparotomy, and, indeed, in cases of an operation for an appendicitis, in the afebrile period of the disease, the stay in bed was shortened to eight or ten days. He could bear witness to the fact that post-operative complications were very much rarer with this change in the management of the patient, pulmonary complications being especially less frequent and less severe than formerly. He has found that the cicatrices were just as firm, and cases of phlebitis and embolism were no more frequent than formerly.

Professor Segond on the contrary saw great danger in the practice recommended by M. J. L. Faure, while M. Moty supported the opinion of the latter. M. Moty was able to quote his own experience; having been operated upon for appendicitis at the age of fifty-six years, he left the bed on the seventh day after the operation. He thought that as far as older patients are concerned, it is a great advantage to have them leave the bed early so as to make them more able to cope with any possible pulmonary congestion.

M. Pierre Delbet thought that the practice of allowing the patients to sit up on the third or fourth day after a median laparotomy was altogether irrational, because in the sitting position not only the abdominal pressure is increased, but that in addition the abdominal walls are wrinkled in such a manner as to interfere with the favorable evolution of the cicatrix.

M. Le Dentu said that after a successful laparotomy he allowed his patients to leave the bed about the fifteenth day after the operation. After any graver operations they were compelled to keep to their beds for at least twenty days. In his opinion, a sufficiently long period of rest in bed saves the patient from unnecessary fatigue and results in an uncomplicated and rapid convalescence.

M. Mauclaire thought that post-operative embolism is of much more frequent occurrence in persons who were allowed to leave their bed early after an operation.

M. Hartmann makes his patients leave the bed on the fifteenth day. He thinks that this best protects them against the complications which are predisposed by the dorsal decubitus of the patient, especially those involving the pulmonary system.

SURGICAL KNOTS.

To the Editor of the Medical Record:

Sir:—In the article on the above topic in this journal, June 6, Dr. Chas. H. Duncan gives a very good series of drawings showing how a knot may be tied quickly by manipulations carried on largely with one hand. The procedure there described has been known here for several years. I have seen it demonstrated also by Dr. E. C. Henry of Omaha.

There are several inherent faults in this method. In pointing them out I will not occupy space by reproducing drawings of the different steps, but will refer by number to the figures in Duncan's article. No one except a novice ties a knot such as the "granny knot" (Fig. 2). That will be left out of the discussion.

In surgical knots the chief point is security. While tying the second half of any knot whatsoever, the operator should keep his eyes fixed on the already partly tied knot until the second half of the knot is completed. If this is done while the manipulations are all carried on with one hand, the other being held steady, as represented in diagrams 4 to 12, the knot will be seen to slacken. Try it and see. Both ends of the ligature should be relaxed during the tying of the second part of the knot in order to avoid this slackening. This means, therefore, that no one-handed manipulation should be used during the tying of the second half of any knot. Given the first half of the knot tightened securely, further manipulations being now carried out with both hands while the ends are slack, the two ends should be grasped in the hands, with the thumbs close to the knot, and the final tension should be put on both at the same time, the eyes still being fixed on the knot.

By referring to Fig. 8 and Fig. 12 it will be seen that if tension is put equally on both ends of the ligature one end remains straight and the other end passes around it in the form of a loop, or, as one observer says, "the knot is all on one string." After placing the hands in the position there shown the reader will find that by crossing the hands the error seen in these figures can be corrected, but to cross one's hands is an awkward procedure. It will be found further that, given the knot half completed by manipulations of the left hand (Figs. 4 to 8), if the second part of the knot is completed by similar manipulations carried out by the right hand, the knot will eventually appear properly tied, as shown in Fig. 1; but a careful observer will notice that the transformation in the appearance of the first half of the knot (Fig. 8) to that of the first half of Fig. 1 is accompanied by an inevitable loosening of this part of the knot, just at the moment that final tension tightens the second half. This is a fatal error in the method. However, as far as the first half of this knot is concerned, by referring to Fig. 4 it will be seen that, by grasping the right-hand end of the ligature with the left hand, while the left-hand end is held with the right hand, the ends crossed with the right-hand end between the operator and the other end of the ligature, if the manipulations are carried out exactly as described by Duncan, the first half of the knot will be properly tied. This accomplished, both ends should be relaxed and the second half of the knot tied as I have described above.

As for the knot called "surgeon's knot" (Fig. 3) and the manipulations (Figs. 13 to 15), few surgeons would leave the knot tied thus except in using silkworm gut in the skin. For all other skin sutures, and all buried sutures and ligatures, a second half knot should be added while both ends are slackened, as referred to above.

THE ETIOLOGY OF CANCER.

To the Editor of the Medical Record:

Sir:—As far back as the early nineties I discovered that among my patients whom I was treating for cancer there were some who exhibited a symptom which I had demonstrated to be a clinical sign of syphilis, namely, the egg-skin eschar in the mouth and upon other mucous surfaces. At a later date I was able in some cases to find an additional evidence of syphilitic infection, which was the presence in the blood of the crypta syphilitica. I also observed that all cases of cancer in which one or both of these clinical signs of syphilis existed bore antisyphilitic treatment well, and that the cancerous symptoms improved by its use. Several patients while under this treatment became well and remained so.

Since that time it has been my rule in practice to use the mixed treatment in all cases of this class, and I feel confident that it is to this fact that my gratifying percentage of success is due. Because I continued to find clinical evidences of syphilis in the majority of my cancer cases, of whatever form or location, and in all cases of epithelioma, and because antisyphilitic treatment improved all cases and even cured some in the early stages, I feel warranted in the conclusion that the real, underlying cause of cancer is syphilis.

As a matter of record and to establish the priority of my discovery in case some other physician should make it independently, and claim it as his own before I could sufficiently verify it and place it before the profession in a proper manner, I imparted my discovery personally to Drs. J. N. Farrar, Robert L. Watkins, John B. Rich, G. H. Patchen, Frank L. Tucker, and others. As it is very likely that I shall not be able to complete my studies and investigations regarding the etiology and elimination of cancer for some years to come, I have decided to give to the profession this brief outline of my theory, for what it may be worth.

G. Lenox Curtis, M.D.

Births and Deaths in England and Wales.—The report of the Registrar-General for 1905, recently issued, shows that the estimated population of England and Wales in 1905 was 34,152,977. From 1901 to 1905 the number of births exceeded the number of deaths by 1,730,576. The births registered in 1905 numbered 929,298, and were in the proportion of 27.2 per 1,000 of the total population of both sexes and all ages; this is the lowest rate recorded since civil registration was established. The deaths registered in England and Wales during the year 1905 numbered 520,031, and were in the proportion of 15.2 per 1,000 persons living. The rate was the lowest rate recorded since civil registration was established.

Progress of Medical Science.

Boston Medical and Surgical Journal, June 18, 1908.

Carcinoma of the Bladder Treated with Trypsin.—R. H. Gilpatrick reports two cases. Patients were women, aged, respectively, 44 and 78 years. In the younger woman an abscess was opened in the left groin, while a carcinomatous growth of utterly inoperable proportions involved the bladder and anterior vaginal wall. Treatment with trypsin injections was begun three days after operation. At first 10 minims were injected into the body of the tumor on alternate days. The dose was rapidly increased to 25 minims, a little cocaine being added to the injection to control pain. The patient grew rapidly worse and was finally sent home to die. The trypsin was apparently without any effect whatever. In the older woman the same general plan was followed and she seemed to improve for awhile, but later she failed and finally died from metastasis at the pylorus.

Modern Medicine and Surgery in the Orient.—J. Ewing Mears, in an interesting account of his travels during the past eighteen months in the Far East, says that in the beginning the art of surgery was advanced to quite a high degree in some parts of the Orient. From this beginning in the East medicine came into the West through the school of Alexandria and the teachings of Galen, of Celsus, and of Paulus of Ægina. To comprehend the position of modern scientific medicine in the Orient we must have a knowledge of the institutions engaged in teaching. In Japan education in medicine is a part of the general system, which is as complete in its development as may be found in any country of the world. The educational center is Tokyo, where one of the greatest universities of Japan is located, the other being in Kyoto. Of the 131 professors in the University of Tokyo, the College of Medicine has 24, with four or five hundred students. There are two hospitals connected with the college, having a total capacity of 571 beds. In addition to the College of Medicine of the university there are eight other medical colleges. Foreign physicians, who are graduates of medical colleges having a reputable standing, will on application be granted a license to practise. There are a number of hospitals outside of those connected with the medical colleges. There is a training school for nurses connected with the Red Cross Hospital. They receive a very practical instruction by lectures and demonstrations, and are made nurses and not half doctors. In no other part of the world is the Red Cross Society so perfectly organized or so efficiently equipped. The society owns two hospital ships. It is the largest in membership, as well as the richest Red Cross organization in the world. Japan also has a well-equipped school for the instruction of its medical military officers. In China, outside of the few hospitals and fewer medical colleges connected with them under British or American control, modern medical science does not have a very firm foothold. The Canton Hospital, which was opened in 1835 by Dr. Kerr, a missionary, has had a place in the records of surgery for many years by reason of the large number of cases of vesical calculi operated on by Dr. Kerr. In Canton sanitary regulations are not enforced, but, in marked contrast to this, one sees much in Shanghai which gives evidence of the influence of Western civilization, especially outside of the Chinese part of the city. There are four hospitals. Bombay is the seat of the Grant Memorial College, the largest of the four medical colleges of India. Connected with the colleges are hospitals used in conducting clinical and laboratory instruction. The teachers in the colleges and the staffs of the hospitals are taken from the medical officers in the Indian Military Medical Service. The medical colleges are in affiliation with the universities, which constitute the head of the educational system carried on by the British government. Very few Mohammedans enter the medical profession. The government refrains, except in extreme conditions, from the enactment and the execution of various desirable laws and sanitary regulations calculated to disturb the uneasy sensibilities of the natives.

New York Medical Journal, June 20, 1908.

Cholera Infantum.—L. K. Hirschberg refers to this malady as an avoidable plague, which each year kills 50,000 babies in this country alone. Nothing particularly new or novel is brought out in the paper. He recognizes the Flexner-Harris organism as responsible for the most virulent and dangerous form of cholera infantum. He considers this organism as practically identical with the Shiga bacillus. The author has nothing new in the line of treatment to present, but believes that before long a protective vaccine will be perfected.

Treatment of Infantile Paralysis.—C. R. Keppler enumerates as the principles of treatment: (1) active treatment by the pendulum machine, massage and electricity, and hydrotherapy; (2) brace treatment, and (3) operative treatment. The pendulum machine is described in full, and the paper is an elaboration along the lines indicated above. Under the head of operative treatment, he enumerates tenotomy, tendon transplantation, nerve transplantation, and arthrodesis. He believes that with sufficient care and the rational use of the treatments herein tabulated—but especially the active pendulum machine and massage treatment, combined with the application of a correct brace—we can in most cases of infantile paralysis be quite optimistic in regard to the recovery of usefulness of and restitution of muscular power in the affected limbs. Certainly it seems plausible that we can hope to attain much better functional results if we actively teach the child to help itself, instead of leaving it in ignorance of its capabilities, without even considering the remarkable local regeneration and immediate gain in general health and strength, which the author has so frequently noted, following the systematic use of the pendulum machine and massage treatment.

The Duodenal Bucket and Direct Examination of the Pancreatic Secretion.—The idea presented itself to M. Einhorn of having beads of different sizes attached to silk threads and having them swallowed in order to see whether they would pass the pylorus. In normal conditions they do so pass, but in stenosis they remain in the stomach. As the length of the thread was not a sufficient guide, he loaded the beads with methyl blue and coated them with tallow. As the fat is mainly dissolved in the duodenum, a green or blue urine would show that the bead had reached the duodenum, that is, had passed the pylorus. In this way, using different substances in the beads and variously coating them, and by using a control bead with a thread of such length that it cannot go beyond the stomach, it can be determined whether or not the pylorus is patent. The pancreatic function is tested in the following manner: The duodenal bucket, tied to a string marked at 75 centimeters, is placed in a gelatin capsule and given about one hour after a small meal. It is left in the digestive tract for three hours without taking any more food. The thread is fastened so that it cannot go beyond the 75 centimeter mark. After three hours the thread is slowly drawn up. In many cases a slight resistance can be felt when the bucket passes the pylorus, the cardiac end usually offering no resistance.

Journal of the American Medical Association, June 20, 1908.

The Eye and Autointoxication.—G. E. de Schweinitz and C. A. Fife publish six fully reported cases of keratitis, chorioiditis, and uveitis, with detailed laboratory examinations of urine, feces, and gastric contents, in which the clinical history and results of treatment seemed to indicate an autointoxication as an etiological factor. Admitting that there is no one disease of the eye that can be considered characteristic of intestinal intoxication, and that laboratory examinations have not isolated any definite toxin to which any of the eye disorders considered can be attributed, the authors believe there is still a fruitful field of study in this direction. We can learn whether or not there are evidences of intestinal putrefaction and can become acquainted with the patient's nitrogen metabolism. If it is found abnormal it can be restored to the normal by a dietetic regimen which could not have been worked out without such study, and we may obtain brilliant therapeutic results in the treatment of the ocular disorder, as is strikingly demonstrated in the majority of the cases reported. They emphasize, however, the need of thorough investigation, and of avoidance of loose interpretation of the facts and routine treatment. Each case must be thoroughly studied by itself and the patient treated accordingly. They also call attention to the relationship which exists between the outbreaks of uveal tract disease, notably chorioiditis and lesions of the skin, which was notably illustrated in one of the cases reported. When the skin affection was evident, the eyes were better, and *vice versâ*. They refer to other instances and remark that this association of eczema, herpes zoster, acne, and chorioidal disease seems to be more than a coincidence. If it be true that an intestinal intoxication may sometimes be interpreted in an effort of elimination by a skin disease, such as those mentioned, is it not probable, they ask, that it may have a similar interpretation by the development of a chorioiditis or a uveitis, and that sometimes the toxin is responsible for the skin lesion, and again, on another occasion, for the ocular disorder?

Marriage of Consumptives.—I. A. McSwain thinks that the factor of heredity is the chief one to be con-

sidered in the strife against the propagation of tuberculosis. It outranks all others, in spite of all that has been lately said to the contrary. Admitting this, it would seem rational that our first efforts ought to be to put a stop to the propagation of those thus predisposed. A tuberculous man or woman ought not to marry on account of the risk of infection to his or her married partner, and this ought of itself to be a sufficient reason against such alliances. But beyond this we have the danger to the offspring, which, serious enough when one parent is a victim of the disease, is increased fourfold when both are tuberculous. There are still other good reasons why consumptives should not marry, for example, the dangers of child bearing and the detrimental effects of sexual intercourse. While something can be accomplished by education, restrictive laws against the marriage of the tuberculous will be needed to reach those who will not voluntarily deny themselves for the public good and the welfare of posterity. McSwain believes a national law would be required to be effective, but we should do what we can in the way of educating the public as to its necessity.

Thymic Asthma.—J. Schwinn reports a case of thymic asthma successfully relieved by operation. Though we know little in regard to the function of the gland, the fact that it is practically always present in normal infants, while Bourneville found it absent in twenty-five out of twenty-eight mentally deficient ones, gives us reasons for treating this gland with the same respect on the operating table as we do the thyroid, and it is wise to leave a portion of the gland behind in thymectomy. The literature of thymic asthma has become quite voluminous; it is doubtless due in most cases to pressure of the enlarged gland on the trachea, though the pressure on other structures, the large veins, the pneumogastrics, etc., is also a probable factor. The symptoms are those of an obstruction in the air tract between the larynx and the tracheal bifurcation. They may become dangerous at any time and, in Schwinn's opinion, may be a more frequent cause of sudden death than is generally supposed. The radiogram is the most trusty of diagnostic aids, and prompt operative interference the best treatment. He briefly summarizes six cases of operation for this condition collected from the literature and reports his own case, in which, besides the thymus, a small portion of which was left for physiological reasons, a part of the hypertrophied left lobe of the thyroid was also removed. The results in all cases were good.

The Lancet, June 13, 1908.

Note on a Case in Which the Widal Reaction Persisted Seven Years After an Attack of Typhoid Fever; Associated with Suppurative Cholangitis, Typhoid Bacilli Being Found in the Bile Passages.—The title of D. E. Core's paper gives the full sequence of events. His patient was a woman of flabby build, whose sickness begun with biliary colic. She was admitted to the hospital with a diagnosis of typhoid fever. Death ensued on the fourteenth day after admission. Pus taken on autopsy from the intrahepatic bile passages showed the *Bacillus typhosus*. The two points of interest are the long persistence of the Widal reaction and the danger of such a patient to the community. She had had typhoid fever seven years before.

The Treatment of Gangrene in Strangulated Hernia at St. Thomas's Hospital, 1901-1905.—Statistics are given by E. M. Corner of 216 cases of strangulated inguinal hernia during the period named. Gangrene was recognized in 8, with a mortality of 3.6 per cent.; of 133 cases of strangulated femoral hernia in 12, with a mortality of 9 per cent., and in 46 cases of strangulated umbilical and ventral hernia, in 10 with a mortality of 21.7 per cent. The treatment of choice has been that of resection and immediate anastomosis. Of such cases 18 have been operated on, with 8 recoveries. During the period there were 10 cases of resection and enterostomy, with only 1 recovery. The author believes that in this general class of cases there are variations of degree in the septicity of the bowel and its contents in cases of intestinal obstruction which have been acute from the beginning, as in the strangulation of a hernia and when the acute obstruction has merely been imposed on a chronic, as in bowel carcinoma. In the former case the septicity is localized in the vicinity of the obstruction, so that if the resection is done freely more or less healthy tissue will be sutured and success will be attained. In the latter case the septicity extends further and all plastic operations like anastomoses are done in a septic area and end in failure.

The Treatment of Intractable Hay Fever and Paroxysmal Coryza by Resection of the Nasal Nerve.—E. S. Yonge describes the anatomical distribution of the nasal nerve in great detail. He says that the relief often afforded in this class of patients by cauterization of the nasal mucosa in the region supplied by the nasal nerve corroborates the suggestion that the terminal filaments of this nerve represent the starting point of reflex disturbances. By bilateral resection of this nerve the author has been able, completely and lastingly, to abolish the symptoms complained of. He thus describes the operation: Chloroform anesthesia; the nerve is reached by an incision at the inner angle of the orbit, commencing just above the inner canthus and extending upwards and slightly outwards for about two-thirds of an inch. By means of a blunt dissector the cellular tissue is cleared from the inner upper wall of the orbit and the nerve located at the anterior orbital foramen is separated from the anterior ethmoidal artery and divided close to the foramen, about a quarter of an inch of the nerve being resected. Horsehair sutures are introduced (removed on the fourth day) and the wound sealed with collodion over gauze. Both sides may be operated on at the same time.

British Medical Journal, June 15, 1908.

Rigor Mortis in the Stillborn.—A. Tarleton was called to a patient in labor at full term. She had been having inefficient pains for three days. The os was fairly well dilated and the cervix was quite soft. The membranes were ruptured by the accoucheur, and in one hour after his arrival a well-developed girl was born. As it did not cry or make any movement, he introduced his finger into its mouth, and was at once struck by the difficulty of doing so, the muscles of the jaw being firmly contracted. After repeated slappings there was no response, and on further examination the child was found to be quite dead. The arms and legs were flexed, and resisted the attempt to straighten them; the muscles of the back, neck, and abdomen were flaccid, and the eyes were quite dull.

Perforated Gastric Ulcer; Operation; Recovery.—R. M. White's patient was a woman of 40 years. The notable features of the case are thus summarized: (1) The mobile dullness on percussion noted at one time in the left iliac fossa, and at another time in the right iliac fossa, making the diagnosis difficult, but Sargeant has called attention to this point in cases of perforation of the stomach. (2) The size and situation of the ulcer: According to Osler the largest ulcer recorded is that reported by Peabody, which measured 19 by 10 cm. In White's case here reported the ulcer was located on the anterior surface of the lesser curvature at the cardiac end of the stomach. It extended up to the commencement of the gullet and was about two and a half inches in diameter, the perforation being the size of a pea. (3) Closure of the perforation: The imitation of nature in closing the perforation by means of an omental graft has been previously recorded, and in cases similar to the above seems to be the most rational method. (4) After-treatment: During the first week, when no food was given by the mouth, the patient exhibited the greatest endurance, and at the end of that time she stated that if food was injurious to her she could manage quite well without it for a few days.

Berliner klinische Wochenschrift, June 8, 1908.

Intestinal Dyspepsia.—Einhorn understands under this term a disturbance of the functions of the intestine, and separates the manifestations of this condition into two groups: the first one shows disturbed function in relation to all three of the elements of foodstuffs, proteid, fat, and carbohydrate; the second group includes conditions in which one or more of the elements are badly taken care of by the bowel. The symptoms may be accompanied by anatomical lesions of the gastrointestinal tract or may be perfectly functional in nature. The best procedure for diagnosing such conditions is the bead test devised by the author. He reports seven cases, two of which show that a complete intestinal dyspepsia may exist for a long time without endangering the life of the patient. Disturbance of the starch digestion seems to be the most frequent trouble in the second group of cases. The therapy of total dyspepsia should consist in a fluid or a semi-fluid diet, and the administration of ferments to make up partially at least for the lack of them in the natural intestinal secretions of the patients.

Intramuscular Myeloma in Myelogenous Leukemia.—Frugoni describes a very rare lesion occurring in myelogenous leukemia. During the course of two cases observed by him a thick intramuscular hematoma appeared, ushered in by shooting pains in the extremity

and general aggravation of the primary disease. Surgical interference led only to the intensification of local and general symptoms. Death followed in both cases, and the histological examination revealed that the hematoma was due to the existence of an intramuscular myeloma, as a metastatic phenomenon of the original blood disease. The author thinks that this lesion is of the gravest prognostic value, and that the possibility of its appearance adds greatly to the support of Banti's theory of the leukemias, namely, that they are neoplastic diseases.

Münchener medizinische Wochenschrift, June 9, 1908.

Vaginal Cesarean Section.—Lunckenbein says that the application of "high forceps" is a dangerous and a difficult procedure when the physician has not received special training in such obstetrical operations. Perforation of the child's skull is not to be performed if any other method of delivery with the preservation of the child's life is possible. He recommends the following procedure instead of these two: The anterior wall of the uterus is split open without the separation of the vaginal vault and without interference with the bladder. Delivery with the forceps or extraction of the child by the foot then follows. Döderlein has used this modification of the operation of Dührssen three times and the author six times, twice in such circumstances that the more extensive dissection called for by the method of Dührssen could not be thought of. The technique consists simply in pulling down the cervix with a bullet forceps and the splitting of it in the middle line with the scissors; the wound edges are then grasped as high up as possible and the anterior uterine wall pulled down, the bladder separating spontaneously. The uterus is now split a little further until the forceps may be used without danger of extensive lateral tears. The wound is sutured after the delivery of the placenta, the bleeding usually not being very extensive. The operation is much simpler than the cesarean section of Dührssen and therefore ought to find a wider field of application. To distinguish it from the former procedure the author proposes for it the name "anterior hysterotomy."

Deutsche medizinische Wochenschrift, May 21 and June 4, 1908.

Indications for Abortion.—Friedmann says that at the present time only typical psychoses of pregnancy are considered as an indication for the induction of an abortion. He thinks, in agreement with Jolly and Pick, that a more important indication for this procedure is found in the "psychopathic reaction" observed in some individuals, which results in a very much exaggerated and morbid fear of childbirth. This reaction differs from the normal anxiety felt by many pregnant women by its intensity, by the tendency to suicidal acts displayed by the patients, and, finally, by the long duration of the depressive state, which may not change for the better in many months. It differs from the real psychoses by being due to the psychical effect alone and by being easily cured with the disappearance of the cause for the morbid and exaggerated anxiety. Induction of abortion resulted in prompt recovery in five of Friedmann's cases, though a relapse followed in one case. The dangers of this affection consist in the possibility of suicide and the great weakening of the patient because of the morbid mental state. As a stay in the insane asylum can meet only the first danger, the induction of abortion is justified in such cases, and, moreover, it fully meets the legal conditions limiting the recourse to this procedure.

Parabiosis and Pancreas Diabetes.—Forsbach says that after a total extirpation of the pancreas in dogs glycosuria sets in within twelve hours. He united two young dogs by their peritoneal cavities, using the method of Sauerbruch and Heyde, and removed the pancreas of one dog after the union was complete. In the next thirty-six hours the depancreatized animal excreted no sugar, while the other one excreted traces of sugar. The death of the depancreatized animal ended this experiment. He repeated the experiment with two other dogs. Neither animal excreted sugar for the next forty hours, after which a slight glycosuria appeared in both animals. After five days the animals had to be separated and the pancreatized one excreted more sugar in the twenty-four hours preceding his death than in all the five days before the separation. The author concludes that parabiosis with a healthy animal may prevent or diminish the appearance of glycosuria in a depancreatized dog.

Pneumatosis Cystoides Intestinorum.—Gröndahl says that certain chronic diseases, such as gastric or duodenal ulcer, chronic volvulus, etc., are sometimes accompanied by the appearance of a great many cysts containing gas, and most abundant in the sigmoid. This condition is probably due to an infection with a gas-forming bacillus, which, however, is not virulent, and has nothing in common with the bacillus of malignant edema. The formation of gas takes place in the lymph vessels and spaces, which are thus changed into cyst-like structures. The changes are very chronic, some cysts being absorbed, others organized. Very few symptoms accompany this curious infection. Gröndahl describes a case and gives several pictures of the lesions present.

Scopolamine-Morphine Anesthesia in Obstetrics.—Krönig says that anesthesia is indicated in the delivery of many women who are either very much weakened by a hard struggle for existence or belong to a type of the highly nervous, sensitive women who are unable to bear the pains of labor without being profoundly and dangerously affected by the suffering. In the Freiburg clinic over 1,500 women have been delivered with the use of scopolamine-morphine anesthesia. The solutions used are a 0.03 per cent. watery solution of scopolaminum hydrobromicum as a 1 per cent. solution of morphine. The first injection is made when the pains recur every four or five minutes, 1½ c.c. of the scopolamine solution and 1 c.c. of the morphine solution being used. One hour later scopolamine alone is injected in a somewhat smaller quantity. Half an hour later the woman is tested as far as her psychic reactions are concerned, various questions being addressed to her in reference to matters that happened just before labor, the number of injections she had received, etc. The injections are repeated if a subject is retained in the mind for over thirty minutes. No untoward action whatever has been observed in any of the 1,500 cases; the single death that has occurred was due to a delivery in the presence of a deformed pelvis, cesarean section being refused by the patient's husband. The loss of blood did not exceed the usual amount; the duration of labor was not affected; the mortality of the infants intrapartum has been diminished by the anesthesia. Krönig concludes that his method of administering scopolamine-morphine in cases of labor fully attains the aim of the procedure, a painless delivery without any harmful effect upon the mother or the child.

The Sphygmobolometer.—Schulthess describes a new instrument devised by Sahli for the examination of the heart. It can no more than any other instruments give the diagnosis of heart diseases, but furnishes the most reliable data as to the efficiency of the left ventricle of the heart, which data may be expressed in numerical values for comparative studies. The instrument allows the comparison of the heart's work in health and in disease, the effect of drugs upon the heart, and the changes in the work of the heart in different positions of the body.

Unilateral Hyperhidrosis.—Friedländer says that unilateral hyperhidrosis is due to a unilateral disturbance of the innervation of the sudorific glands. There are a central and a peripheral type of such disturbance. Both forms may occur in isolated cases in healthy individuals as well as in persons suffering from various diseases and are characterized by an extremely chronic course. The disease is essentially unimportant and harmless in character. The author reports six cases of the affection observed by him.

Atropine and the Slow Pulse.—H. Vaquez says that the careful study of arrhythmia enables us to detect in most cases a nervous origin for the trouble, in others a muscular origin. In case of nervous origin there is an entire pause in the beats, while in the muscular affections auscultation and the comparative study of the traces of the radial and jugular show a slowing of the beat which only affects the ventricle, the auricular contractions producing systoles like an echo of the ventricular contraction. In a healthy man atropine accelerates the beats of the heart. When the pulse is slowed by disease atropine will cause a paralysis of the terminal filaments of the pneumogastric in the cardiac muscle and the beat becomes quickened. In bradycardia caused by organic muscular lesion the effect of atropine is nil. The rhythm is not modified at all. The author presents a case in which atropine showed the purely nervous origin of the trouble, the slowing having shown itself in the course of an appendicitis.—*La Tribune Médicale.*

Book Reviews.

Hernia, its Etiology, Symptoms, and Treatment. By W. McAdam Eccles, M.S. (London), F.R.C.S. (England), Assistant Surgeon to, and Demonstrator of Operative Surgery at, St. Bartholomew's Hospital; Examiner in Surgery to the Society of Apothecaries; Examiner in Anatomy for the Fellowship of the Royal College of Surgeons of England; late Hunterian Professor of Surgery, Royal College of Surgeons of England; Lecturer on Anatomy, St. Bartholomew's Hospital; Senior Assistant Surgeon, West London Hospital, and City of London Truss Society, etc. Third Edition. New York: William Wood & Co., 1908.

The third edition of this work has just appeared, thereby evidencing a deserved popularity. No great alterations have been made, it being as before a short account of the origin, symptoms, and treatment of hernia, incorporating many practical suggestions. The author, however, devotes more attention to the nonoperative treatment of hernia than in the previous editions. He gives a detailed description of the truss treatment of all types of hernia, such as can be found in none of the textbooks on surgery and a subject very meagerly treated in the different systems of surgery of the present day. The illustrations serve to graphically supplement the text. Descriptions of operative technique can be found in all books on surgery; not so the indications for operative interference and postoperative treatment; the latter subjects, however, are well worthy of careful reading in this publication. The book cannot be too highly recommended to the surgeon as well as to the general practitioner.

Minor Maladies and Their Treatment. By Leonard Williams, M.D., M.R.C.P.; Physician to the French Hospital; Assistant Physician to the Metropolitan Hospital; late Assistant Physician to the German Hospital; and Hon. Medical Officer to the Sidmouth Cottage Hospital. Second edition, revised and enlarged. New York: William Wood & Company, 1908.

The average medical student graduates with fair knowledge of the symptomatology, the diagnosis, and the treatment of the more serious diseases, cases of which he has seen in the hospitals and dispensaries. On the other hand, he is usually quite at sea when confronted by the minor ailments of mankind; he either misinterprets their symptoms into those of serious disease or finds himself untrained in relieving the usual discomfort of the patient. Dr. Williams's little book, therefore, has its distinct field of usefulness in helping the young physician until riper experience enables him to decide upon his own plan of treatment of minor maladies. The first chapter of the work is devoted to "colds, coughs, and sore throats," specific therapeutic advice being given and complete prescriptions written out instead of the usual list of drugs "good" for the complaint. The next two chapters consider the commoner diseases of the gastrointestinal tract, indigestion, constipation, and diarrhea being given most attention. The many manifestations of "rheumatism and goutiness" are next considered together with neuralgia and headache; in the case of the latter the various etiological factors are fully entered into. Change of air, questions of general health and hygiene, the properties and uses of the more important drugs, and some phases of insanity are discussed at the end of the book. A very complete index makes the work handy for ready reference. The book ought to prove very useful to the student and the young practitioner.

Considérations Historiques sur la Blennorrhagie, par le Docteur Ernest Roucayrol, Médaille de Bronze de l'Assistance Publique, Membre de la Société Française d'Histoire de la Médecine. Paris: G. Steinheil, 1907.

While this book of 239 pages is interestingly written, it does not come up to the promise of its title. Indeed, if its ancient history, which but few would take time to verify, is as incomplete as the recital of modern work, the history of gonorrhea is not materially enriched by the author. In this connection it may be mentioned that Guyon's name does not appear in the book; Janet is recalled by the fact that a syringe devised by Bertrandi (A.D. 1786-1802) is thought by the author to resemble the one Janet presented to the profession some twelve or fifteen years ago. To the unimaginative reviewer the picture resembles the instrument used by veterinarians for horses, as much as it does Janet's syringe. If the term "European Chauvinism" is admissible, the author certainly has it, because the names of Noegerrath, Bumstead, Keyes, Taylor, Sturgis, Fuller, Lydston, and other American writers who have contributed important additions to the study of gonorrhea do not appear. It is to be hoped that the ancient history of this book is not as inexact as the more modern period which he recites, as shown by the illustration of a discarded form of the Valentine urethroscope that Dr. Roucayrol presents as devised by Luys (pp. 216, 217). The book, however, is not without value; it can serve as an aid to tracing the historical origin of thought on gonorrhea. The vast amount of research devoted by the author to European, and especially French, literature, will certainly help those interested, more particularly when the field examined by Roucayrol is not accessible to them.

Atlas der gynäkologischen Cystoskopie, von Dr. W. Stoeckel, Direktor der Universitäts-Frauenklinik in Marburg, a. L. Mit 14 lithographischen Tafeln. Berlin: August Hirschwald, 1908.

This book, essentially one of illustrations by Miss L. Krause (except one by B. Fritsch, Jr., and another by Kawasoye of Japan) is presented as a supplement to the author's work on "Cystoskopie der Gynäkologen." The 70 pictures of the normal and diseased bladder it contains are certainly made with great precision, although in some instances the colors employed are rather high. This excess of coloration, however, is materially modified towards the cystoscopic appearances, when examined by electric light. The essential inconveniences of this work can be remedied in future editions by reducing the types of the text, so that it will in each instance confront the illustration to which it refers. The descriptions are concise, in some places too terse for the beginner in cystoscopic diagnosis. It will prove a most valuable addition to the experienced cystoscopist's library.

A Text Book of Otology for Physicians and Students in 32 Lectures, by Fr. Bezold, M.D., Professor of Otology at the University of Munich, and Fr. Siebenmann, M.D., Professor of Otology at the University of Basle. Translated by J. Hollinger, M.D., of Chicago. Chicago: E. H. Colgrove & Co., 1908.

In this work the author demonstrates the typography of the middle ear principally by cuts of specimens from his work "Corrosion Anatomy of the Ear," but omits a description of the ossicles and their relations to each other and assumes that the reader has a knowledge of the labyrinth and its contents. In Lecture IV he gives rather a full description of the technique of examinations through the Eustachian tube and describes eight methods of passing the catheter. Lecture V discusses in an original way the shape, size, and curves of the external auditory canal, and includes careful observations of the normal reflexes of the membrana tympani. The statistics collected from school children and army men, relative to functional disturbances of hearing determined by means of tone tests, is full and very practical. The diseases of the external ear, the external meatus, and the tympanic membrane are treated in the lectures from X to XV. From Lecture XV to XXIV the middle ear and its diseases receive very careful consideration, but as the book is designed for the general practitioner the operations are not given in detail except Schwartze's for opening the antrum. The diseases of the inner ear were taken up by Prof. Siebenmann because of the illness of Prof. Bezold. The four lectures comprising his contribution form a valuable part of the course. Many books are published on otology of larger size and more generous padding, but few are more up to date and condensed. The translation is well done, but there are some typographical errors which will doubtless be corrected in the next edition.

Manuel Pratique et Simplifié d'Analyses des Urines, et Autres Secretions Organiques. Par Ernest Liotard, O.I., Docteur en Médecine à Nice. Third Edition. Paris: A. Maloine, 1908.

Liotard's manual of urine analysis, etc., is intended for students and general practitioners. It is very brief, and cannot be said to aim at completeness of treatment, but it contains the essentials of the subject. In some respects it is unlike the similar books published in English: Much space is devoted to the qualitative relations of the various urinary constituents, especially to the various "coefficients" of which the French are very fond. The chapters on the examination of cystic fluid, serous fluids, etc., are very brief.

Transactions of the Twenty-ninth Annual Meeting of the American Laryngological Association. Held at Washington, D. C., May 7, 8 and 9, 1907. New York: Published by the Association, 1907.

This volume contains the papers and theses presented to the Association and read at the twenty-ninth annual meeting. An interesting presidential address, by Dr. A. W. de Roaldes heads the volume.

Society Reports.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting Held at Richmond, Va., May 5 and 6, 1908.

(Special Report to the MEDICAL RECORD)

THE PRESIDENT, Dr. WILLIAM H. CARMALT OF PITTSBURG, IN THE CHAIR.

Address of the President.—Dr. CARMALT reviewed the advances in pathological anatomy during the past fifty years. He pointed out the advantages to the hospitals of having clinical teaching in the wards and emphasized the need of the establishment in hospitals of fully equipped pathological laboratories. Instances were cited of the transference of pathological conditions from internal medicine to surgery.

Reminiscences of the Early Days of the American Surgical Association.—Dr. J. EWING MEARS of Philadelphia, one of the survivors of the original Fellows of the Association, reviewed its reorganization and history. The suggestion of selecting Washington as a permanent meeting place of the Association was considered with the idea of erecting a suitable building for the purposes of the organization. Practical steps were taken toward the consummation of this idea.

Surgery of the Gasserian Ganglion.—Dr. STEPHEN H. WEEKS of Portland reported two cases of removal of the Gasserian ganglion for the relief of *tic douloureux*. He disapproved of the operation as a primary procedure for the condition, claiming that the extracranial operations upon the branches of the fifth cranial nerve should first be made. There was complete relief from pain in both cases. The escape of a small portion of the brain during one operation had apparently caused subsequent difficulty in the pronunciation of certain names.

Dr. VANDER VEER of Albany had done this operation a number of times with successful issue. Hemorrhage had always been a cause of anxiety to him.

Dr. S. J. MIXTER secured better results in doing the operation in two stages.

Perforative Peritonitis (General, Free, Suppurative).—Dr. JOHN B. MURPHY of Chicago gave particular emphasis to his reference to free, spreading, perforative peritonitis in the consideration of his subject. Only such cases were included in the paper as resulted from (*a*) direct communications of the alimentary canal into the free peritoneal cavity, and (*b*) perforations of the appendix with primary retention of the infective material in a circumscribed zone and subsequent rupture into the free peritoneal cavity with the presence of a communication from the intestine, through the appendix, and through the abscess in the free cavity. Forty-eight cases were operated upon, two gastric perforations, one duodenal, four typhoid, forty-one appendical. The sixteenth and forty-sixth cases ended fatally, the first from a double pneumonia on the sixth day after operation; the second from a mechanical ileus and strangulation of the intestines around the omentum. While Dr. Murphy stated his confidence in the uniformly good results of the future, this involved the assumption of early diagnoses, insistence upon early operation with the least possible trauma consistent with closure of the opening and the relief of pus tension, limitation of the anesthesia, shortening of the time of operation, insuring the continual absence of pus tension, elimination of sepsis already in the blood, restoration of blood pressure, and inhibition of septic absorption by position. The limitation of intestinal manipulation and exposure of the abdominal contents was considered the most important of the elements mentioned. The importance of the Fowler position both preoperative and postoperative the author said was not fully appreciated. He insisted that the patient should be placed in this position when diagnosis was made and so continued until convalescence was well advanced. Opium and coal tar anodynes were not given in the reported series either before or after operation.

Dr. JOHN B. DEAVER of Philadelphia laid particular emphasis upon early operation and a minimum of manipulation. He regarded short anesthesia as important. He used eserine reinforced with strychnine and had no hesitation in sitting patients up in bed. He had no hesitation in reopening the abdomen for obstruction. He was emphatic in his statement that he did not give morphine.

Dr. A. G. GERSTER of New York City had within the past two years followed Dr. Murphy's plan of treatment with markedly improved results. He thought Dr. Deaver's withholding of morphine an extreme position and unwarranted.

Dr. ARTHUR D. BEVAN of Chicago in some cases of fluid in the peritoneal cavity used a female glass catheter as a pipette for taking up the pus. He believed it good surgery to wash out the peritoneal cavity and claimed that it could be done without loss of time. As an anesthetic he favored nitrous oxide gas in preference to ether or chloroform.

Dr. DUDLEY P. ALLEN of Cleveland when draining, in order to have the advantage of gravity, placed the patient upon the side.

Dr. JOSEPH RANSOHOFF of Cincinnati feared that a statement of recovery in the proportion of 44 to 3 would cause the average general practitioner to delay in seeking surgical aid. He inquired in how many of the forty-seven cases operation was done after four or five days after onset of general peritonitis and in how many cases death appeared to be imminent.

Dr. GEORGE E. ARMSTRONG of Montreal regarded induced draining by rectal injection in the sitting position an important factor in treatment. In two cases of persistent vomiting with swelling in the epigastric region reversal of the position of the patients from the Fowler to the Trendelenburg position gave relief.

Dr. JOHN C. OLIVER of Cincinnati referred to the natural difference of opinion concerning the forms of peritonitis following appendicitis or perforated gastric or duodenal ulcer and to the consensus of opinion that peritonitis following gunshot wounds was apt to be general. He inquired whether Dr. Murphy's method had been applied in cases of peritonitis following gunshot wounds of the abdomen.

Dr. JAMES E. MOORE of Minneapolis did not agree with Dr. Deaver in believing that abdominal cases should be deprived of morphia.

Dr. MORRIS H. RICHARDSON of Boston said that in their hospital service they depended largely in the treatment of peritonitis upon rectal lavage. While not following exactly Dr. Murphy's method, they did not wash out the abdomen nor wipe extensively; also they did not make multiple incisions. They gave small doses of morphine.

Dr. JOHN B. ROBERTS of Philadelphia thought Dr. Murphy's paper showed the error in the belief heretofore held that patients should be maintained in the dorsal recumbent position and be deprived of water and pain-obtunding drugs. It also proved that cases of perforated appendicitis and similar lesions should not be treated by an insistent search for the offending organ.

Dr. RICHARD H. HARTE of Philadelphia in drainage preferred gauze to tubes. Even in the typhoid perforation cases in which the perforation occurred at the end of a very long illness he approved of having his patients in the sitting posture.

Dr. M. L. HARRIS of Chicago referred to cases of gunshot wound of the abdomen upon which he had operated. All had been drained and all recovered.

Mr. G. B. A. MOYNIHAN of Leeds, England, referred to their improved results in following Dr. Murphy's treatment. Differing from Dr. Deaver in the matter of mor-

phine a small hypodermic was given in every case before the patient left the operating table. The patient was allowed to take as much water as he wanted.

Dr. MURPHY in closing said positively that every case of general perforative peritonitis if managed correctly should recover. Replying to Dr. Ransohoff, all his cases were under forty hours and added that all should be under twenty-four hours, while under twelve would be even better.

Late Results (Two Years or More) After Operations for Benign Diseases of the Stomach and Duodenum.—Mr. B. G. A. MOYNIHAN of Leeds, England, reviewed the records of his operations in nonmalignant diseases of the stomach. They were 281 in number and a full classification was given with the results obtained. It was concluded from this review that the operative treatment of stomach disorders should be confined exclusively to those cases in which an organic lesion was present. In cases of acute perforating ulcer, the perforation should be closed or the ulcer excised. In his opinion the most satisfactory method of gastroenterostomy was the posterior no-loop operation, with the almost vertical application of the bowel to the stomach.

Study of Gastric and Duodenal Ulcers, with Especial Reference to Their Surgical Cure.—Dr. WILLIAM J. MAYO reported a series of cases in which the average duration of the symptoms was over twelve years and in which medical treatment had been ineffectual. A classification was given of all the cases of ulcer and kindred diseases of the stomach and duodenum operated on between 1893 and April, 1908. There had been 824 operations. With one exception, all of the cases of acute perforation treated by simple suture recovered. There was a mortality of less than one per cent. in more than 300 posterior no-loop gastrojejunostomies with the intestine sutured to the stomach in its normal position downward and to the left. Only three cases had required secondary operation. There had been traced 379 cases of ulcer of the stomach and duodenum operated upon previous to 1906, covering two to fifteen years since operation. In 318 actually demonstrated ulcers 80.7 per cent. were cured, 9 per cent. improved, and 4.2 per cent. unimproved. Six per cent. died from various causes in the year subsequent to operation. In only two was the cause connected with the stomach.

End Results Following Operation for Benign Diseases of the Stomach and Duodenum.—Dr. JOHN B. DEAVER of Philadelphia presented this paper in which the following conclusions were submitted: That the operation of choice should always be performed when feasible; when not feasible, the operation of necessity. All cases of stenosis of the pylorus, due to whatever cause, should be treated by operative interference and preferably by posterior gastrojejunostomy. All cases of ulcer of the stomach not responding promptly to medical treatment, and the cases showing the various sequelæ of the disease should be treated surgically. This was also true of cases of ulcer of the duodenum. In performing gastroenterostomy he preferred the posterior gastrojejunostomy, no-loop clamp route.

How Frequently Do Gastric Ulcers Become Carcinomata?—Dr. WILLIAM L. RODMAN believed that in fifty per cent. gastric carcinomata was the result of ulcer. He had had nine cases of cancer in which there was history of ulcer. The most important diagnostic sign was said to be rapid and regular diminution of hyperacidity. Little was to be ascertained from the gastric analysis as the chemical characteristics might be the same as in simple ulcer. He advocated exploratory operation in all gastric cases of doubtful nature irresponsive to medical treatment.

Gastric and Duodenal Ulcers Secondary to Wounds of the Urinary Bladder.—Dr. JOHN B. ROBERTS of Philadelphia referred to a case which he had previously reported of death from perforating gastric ulcer following suprapubic lithotomy and to a case in which the patient had died from massive hemorrhage due to ulcer of the duodenum following extraperitoneal rupture of the urinary bladder and other injuries. From literature and his own experience he had collected sixteen instances of gastrointestinal bleeding subsequent to operative or other lesions of the urinary organs. Dr. Roberts showed the possible connection between abdominal and pelvic operations and post-operative hematemesis and intestinal bleeding. The etiology of the gastrointestinal lesions considered was regarded as obscure, but probably connected with thrombosis and embolism due to septicemia or toxemia. Experimental and clinical evidence it was said gave credence to the theory that changes in the gastric and intestinal mucosa leading to fatal issue might be the result of several local influences or of widespread pathological alteration in the cells and fluids of the body.

Infantile Hypertrophic Stenosis of the Pylorus.—Dr. FRANK E. BUNTS of Cleveland reported the case of an infant four and a half weeks old in which an anterior gastroenterostomy was done for pyloric stenosis. Recovery ensued. In 114 cases collected by the author and Dr. Thompson there was a mortality of 55.5 per cent. The author advised early operative interference in congenital pyloric stenosis, believing that this gave good chance of recovery.

Dr. WILLY MEYER of New York in the secondary operation preferred gastroenterostomy plus enterostomy to the short loop.

Dr. JOHN H. GIBBON inquired concerning the frequency of peptic ulcer of the jejunum following gastroenterostomy. In a report of over a thousand cases it had not been observed.

Dr. GEORGE W. CRILE of Cleveland spoke of the value of direct transfusion of blood at the time of operation in an unsurgical case, which treatment had made surgical interference possible. In 66 cases the hemolytic test of cancer gave positive reaction in 80 per cent.

Dr. J. M. T. FINNEY of Baltimore regarded the personal equation a determining factor in a choice of operations. He had employed pyloroplasty for pyloric obstruction forty-eight times since 1903. Of these cases four had died, but autopsy showed the cause of death to be other than the operation. He agreed with Dr. Rodman that resection should be done in doubtful cases of ulcer. He believed that gastroenterostomy should be employed in inflammatory pyloric stenosis in preference to pyloroplasty.

Dr. JOHN C. MUNRO of Boston favored the Finney operation.

Dr. JOHN C. OLIVER of Cincinnati referred to four cases of congenital stenosis operated upon by gastroenterostomy. The symptoms in one case appeared two weeks after birth. A family history of stomach trouble for three generations was traceable.

Dr. FRANCIS J. SHEPHERD of Montreal reported a case in which he had done pyloroplasty upon a child three weeks old. The child at eighteen months was perfectly well.

Dr. LEONARD FREEMAN of Denver had used linen thread for the hemostatic suture in about fifty-five gastroenterostomies with satisfaction.

Dr. WILLY MEYER of New York warned against making the loop too long.

Dr. JOHN E. SUMMERS, Jr., of Omaha thought that postoperative gastric and intestinal hemorrhage was probably due to trauma.

Mr. G. B. A. MOYNIHAN said the ulcer should be excised when there was difficulty in distinguishing between ulcer and carcinoma. He employed the posterior no-loop method, making the anastomosis close to the beginning

of the jejunum. He regarded the important point the application of the jejunum to the stomach in a way that it lies easily.

Dr. W. J. Mayo in closing said that the medical man should be urged to turn over early to the surgeon cases of tumor, the character of which he was waiting to determine. He thought the papers showed that 80 per cent. of permanent recoveries could be secured in gastric ulcer with an improvement of somewhat less than 10 per cent.

Dr. William L. Rodman did not believe postoperative hematemesis to be due to trauma but thought the most rational explanation to be that suggested by Dr. Roberts, viz., sepsis.

Stone, Tuberculosis of the Kidney and Perinephritic Abscess.—Dr. George Tully Vaughn of Washington, D. C., enumerated the causes of stone and expressed the belief that stone in the kidney should be removed at once and that impacted stone in the ureter should be removed when it could not be passed. A calculous kidney he believed should not be removed so long as there was any chance of saving it. He advised nephrostomy and drainage in the presence of tuberculosis of both kidneys. If but one was affected, nephrectomy should be done.

Diagnosis and Treatment of Kidney Stone.—Dr. Arthur Dean Bevan of Chicago spoke of the value of the *x*-ray in diagnosis of kidney stone. With definite diagnosis there should be surgical removal except where the stones were small enough to be passed, in the presence of organic lesions, and in cases of extreme age. In fifty-two operations he had had but one death from nephrolithotomy and two from secondary nephrectomy.

Report of a Case of a Large Kidney Stone.—Dr. David Barrow of Lexington showed a kidney stone weighing one pound and two drachms, which had been proven to be phosphatic. Convalesence followed removal of the stone and the man regained perfect health.

Results of Operation on the Kidney for Calculus and Tuberculosis.—Dr. Andrew J. McCosh of New York had performed fifty-four nephrectomies, nineteen of which had been for tuberculosis. Five patients had made perfect recoveries. He had performed forty-eight operations for renal calculi. Septic kidneys or those in a condition of pyonephrosis were not considered. Fifteen nephrolithotomies had been performed by him, in twelve of which cases the patients regained perfect health. In extraction of the stone the route through the kidney is preferred to removal by an incision in its pelvis.

Dr. Leonard Freeman of Denver showed an *x*-ray picture exhibiting shadows resembling calculi in the ureter which he thought might be calcified lymphatic glands, or phleboliths. In operating for stone in the kidney his preference was for the incision through the parenchyma. Bleeding he had found could be easily controlled by the use of the gastroenterostomy forceps with the flexible blade covered with rubber.

Dr. George E. Brewer of New York City thought Dr. Bevan's paper of particular value since it emphasized the fact that there were no symptoms absolutely pathognomonic of stone in the kidney.

Dr. Nathan Jacobson of Syracuse spoke of the confirmatory value of the *x*-ray in diagnosis of renal stone. He reported a case in which in a perineal section there was discovered a complete incrustation of the bladder wall. Autopsy showed both kidneys to be filled with stones.

Dr. C. B. G. deNancrède of Ann Arbor cited a case in which diagnosis by the *x*-ray had proved to be wrong. A case was reported of removal of a large uric acid stone from the bladder. In this case the *x*-ray had given no evidence of its presence.

Dr. Ellsworth Eliot, Jr., of New York City spoke of the probability of osseous development in the ligaments of the pelvis being mistaken for calculi.

Dr. Joseph Ransohoff said he employed the *x*-ray only as a confirmatory test of diagnosis based upon a clinical study. Persistent, continuous microscopic hematuria he regarded as absolutely characteristic of stone in the kidney. He referred to a case in which a ureteral stone was guttered, allowing the urine to pass without difficulty. No operation on the kidney was thought to be complete without the passage of the catheter or probe along the whole length of the ureter.

Dr. Maurice H. Richardson of Boston spoke of the difficulties in diagnosis in surgery which made the subject of greatest interest. Along this line and illustrative of some of the difficulties, he had known cases of stone in the kidney to be fatal twenty-two years subsequent to removal of calculi from the bladder with no pain during the interval. In other cases there had been continuance of pain after removal of stone from the kidney.

Dr. Willy Meyer advocated the use of the *x*-ray in diagnosis of stone after laboratory methods had been thoroughly employed.

Dr. George W. Crile of Cleveland spoke of the value of the direct transfusion of blood following hemorrhage.

Dr. J. M. T. Finney referring to the importance of diagnosis quoted a former Fellow of the Association in saying that "Nine men out of ten know what to do, but the tenth man knows what not to do."

Dr. M. L. Harris of Chicago referred to three cases of bilateral tuberculosis of the kidneys in which he had operated with success.

Dr. Francis J. Shepherd spoke of the difficulty in the control of hemorrhage and of a case in which because of this removal of the kidney was necessary.

Dr. John C. Oliver of Cincinnati showed an oxalic acid stone of large size which until seeing the one exhibited by Dr. Barrow he had believed the largest on record.

Dr. Lewis L. McArthur of Chicago quoted Dr. Senn at the time the *x*-ray was first exhibited in Chicago as saying: "I see the advent of this wonder with chagrin and anxiety, lest the student, finding a short route to diagnosis, will rely entirely upon this means and forget, or neglect, the means which already are at hand." Showing the possibility of mistaken diagnosis by the *x*-ray he cited a case in which operation revealed twenty stones in one kidney, although the *x*-ray examination had shown no shadow.

The Diagnosis and Prognosis of Tuberculosis and Septic Conditions of the Kidneys.—Dr. G. E. Armstrong spoke of the surgical interest of unilateral and primary renal tuberculosis and gave figures showing the improved results in the treatment of the condition.

Acute Unilateral Hematogenous Infections of the Kidney.—Dr. George Emerson Brewer of New York City referred to the probability of this condition being overlooked. In nine cases admitted to the Roosevelt Hospital in only one had the correct diagnosis been made before entrance. Cases were cited which had been subjected to unnecessary operation because of the almost typical symptoms of appendicitis or cholecystitis. The condition was divided into three groups of cases and the characteristics of the cases belonging to the individual groups described with treatment indicated. A marked unilateral costovertebral tenderness was stated to be the one pathognomonic sign observed in all the types.

Dr. Emmet Rixford of San Francisco cited a case in which at autopsy there were shown to be four ureters in three of which were stones. The case had been operated for stone in the bladder. Another case in which a diagnosis had been made of subacute peritonitis operation showed a small kidney in the neighborhood of the vermiform appendix. Tuberculin was suggested as offering possibilities of cure in tuberculous kidneys.

Dr. A. G. Gerster of New York City cited two cases of removal of the kidney after the simple exploratory in-

cision in the pelvis because of uncontrollable hemorrhage. In opening the pelvis through the kidney he had abandoned the use of the knife and opened by means of the curved director with tearing and stretching.

Dr. Frederick Kammerer of New York City referred to three cases of unilateral infection of the kidneys. In the first case recovery followed the removal of one kidney. The second case showed but two infarcts in one kidney while the other was normal. The incised kidney was tamponed and replaced. The patient did well but afterward developed temperature, when extirpation of the kidney was done. In the third case because of perinephritic abscess removal of the kidney was finally necessary. The later condition of the case proved the claim made by Dr. Brewer that the infection could be unilateral.

Dr. John H. Gibbon of Philadelphia referred to the diagnostic value of *x*-ray plates and of the presence of microscopic blood in ureteral calculi. He warned against the danger of the use of metal ureteral bougies. Reference was made to a method he had employed of a combined extra- and intraperitoneal operation.

Dr. Charles L. Gibson of New York City referred to a case in which half of the kidney at each pole was removed in a condition similar to that described by Dr. Brewer. Perfect recovery ensued.

Dr. George Woolsey of New York City did not consider a negative plate an absolute sign of absence of ureteral stone. In two cases operated upon he had found the lesion spoken of by Dr. Brewer and had performed nephrectomy with cure. He spoke of the value of Dr. Brewer's presentation of a new field of pathology and treatment in kidney lesions.

Dr. Bevan in closing said that the diagnostic symptoms were in point of importance as follows: The gross clinical picture, including history; careful ordinary examination of the urine, chemical and microscopical; *x*-ray examination. He believed the *x*-ray could be relied upon in nine-tenths of cases in the diagnosis of kidney stone.

Dr. M. L. Harris of Chicago referring to the use of the segregator said that if urine dropped from the two sides synchronously, whether or not the amount was the same, there was evidently an improper adjustment of the instrument or the presence of an anomaly.

Report of a Case of Stone in the Bladder, Associated with Intermittent Pneumaturia for Three Years, and the Subsequent Formation of Fecal Fistula.—Dr. A. T. Bristow of Brooklyn reported that over two hundred cases of pneumaturia were cited in literature. He reported a case under his observation in which there had been several attacks since 1907. Fecal fistula was present and, except for occasional attacks, the patient was perfectly well, and would not submit to operation.

Dr. Frederick Kammerer reported a case of pelvic abscess which, following an operation and the removal of the appendix, recovered.

Dr. Arthur D. Bevan of Chicago reported a case of an abnormally enlarged kidney shown by the *x*-ray in which operation showed the kidney and calices distended with gas. In another case in which he had removed the kidney within the capsule a stone was found which had penetrated the duodenum. Autopsy showed a perfectly clean peritoneal cavity with an opening into the duodenum which had been produced by the inflammation about the stone.

Dr. George E. Brewer of New York thought some of these cases might be those of diverticulitis.

Dr. Emmet Rixford of San Francisco cited a case of pelvic inflammation, in which following the administration of castor oil peritonitis developed resulting in death. Autopsy showed a diverticulum.

Dr. George Woolsey of New York City reported an operation for stricture of the urethra. The conditions of the case suggested acute diverticulitis following the incision.

Primary Carcinoma of the Female Urethra.—Dr. Lewis S. McMurty of Louisville reviewed the literature on the subject and reported two cases of his own in both of which the disease had originated in the urethra. In both cases there was complete excision of the urethra down to the sphincter muscle of the bladder. There was recurrence in one case but not in the other. Because of the resemblance of the initial lesion to urethral caruncle, early diagnosis was considered difficult. Also the difficulty was pointed out of the differential diagnosis from syphilitic lesions in the same location. He urged habitual examination of all cases presenting painful micturition, early diagnosis of malignant types of disease, with complete excision in the early stage of invasion when permanent cure was possible.

A Case of Melanotic Sarcoma of the Common Bile Duct, and of the Ampulla of Vater.—Dr. Francis J. Shepherd of Montreal reported a case in which there was observed a rounded, painless swelling in the region of the gall-bladder. At operation no obstruction of the bile duct was observed nor were there gallstones nor appearance of malignancy present. Death followed some weeks subsequent to operation. Autopsy showed a fungoid mass completely occluding the common duct and a part of Vater's diverticulum. There was no melanotic growth discoverable elsewhere, nor were there pigmented moles on the body. The suggestion was made of pigment cells having become dislodged from a normal situation and arrested in the bile duct.

Rhinoplasty for Sunken Nose.—Dr. John F. Binnie of Kansas City described an operation he had done for this condition in which he had divided subcutaneously the soft parts and inserted them into the edge of the pyriform opening and pulled the mobilized nose into position. The soft parts of the mobilized nose were then subcutaneously tunneled and strips of cartilage drawn through the tunnels and made to act as trusses supporting the nose.

Dr. John Roberts spoke of a case under his care in which he had taken two large tongue-shaped flaps from the rather fat cheeks of the patient in a somewhat similar operation.

Dr. Leonard Freeman of Denver referred to the type of saddle nose in which the skin is loose and which could be satisfactorily treated by the use of paraffin. Metal plates were employed to better advantage in the type of the condition in which there was cicatrical tissue and tendency to contraction.

Dr. Emmet Rixford of San Francisco had used tissue of the rib in his operations for sunken nose.

Psychical End Results in Major Surgical Operations.—Dr. James G. Mumford of Boston referred to psychic impressions in regard to surgical therapeutics. From a study of 500 eight-year-old records at the Massachusetts General Hospital it was concluded that surgeons should exercise for a longer period than was customary some supervision of their patients following operation. It had been proven by the work of the Emanuel Church movement in Boston that many cases thus watched over could be brought more quickly to perfect recovery.

Further Evidence in Support of the Theory that Hodgkin's Disease Is a Type of Sarcoma.—Dr. William B. Coley of New York City in a study of more than eighty cases of primary sarcoma in the lymphatic glands, concluded that the small group of tumors designated as Hodgkin's disease, or pseudoleukemia, had certain definite clinical and histological characteristics sufficient to differentiate them from other tumors of the lymphatic glands. He believed that because Hodgkin's disease and leukemia had certain features pointing to an infectious origin this should not exclude them from being classed

as malignant tumors. He believed rather that this was evidence of the infectious origin of sarcoma. He believed the best chance of successful treatment lay in a wider application of the *x*-rays and the mixed toxins of erysipelas and *Bacillus prodigiosus*.

The Use of Sterile Oil to Prevent Intraperitoneal Adhesions; a Clinical and Experimental Study.—Dr. John Barst Blake of Boston from his experimental work in this field concluded that there was no danger in the use of absolutely sterile oil in moderate quantities in the peritoneal cavity; that it might remain in the peritoneal cavity for from five to fifteen days, and that adhesions were probably prevented by its presence.

Surgical Aspects of Graves' Disease with Reference to the Psychic Factor.—Dr. George Crile of Cleveland believed that relief or cure would follow the excision of a correct amount of the thyroid gland in Graves' disease. He believed the operative risk, which he claimed was hyperthyroidism, to be the serious barrier to surgical treatment. To insure success the operation should be performed without the knowledge of the patient. Dr. Crile recounted the plan followed in which this idea had been carried out. Thirteen cases had been operated upon by the new method with satisfactory result.

Primary Carcinoma of the Appendix.—Dr. Richard H. Harte of Philadelphia thought there were no signs pointing to this condition other than the classical signs of appendicitis, and believed that a diagnosis of cancer of the appendix prior to an operation was impossible. It would seem to the author that all cases of cancer of the appendix were engrafted upon a chronically inflamed appendix. Primary carcinoma was said to be present in from one-third of one per cent. to one per cent. of all cases of operation for chronic appendicitis. The disease was believed to be slightly more frequent in women than in men. It was urged that all appendices showing evidence of any irritation should be removed since primary carcinoma of the appendix had its origin in an inflammatory process.

Edema of the Large Intestine, with Localized Necrosis of Its Wall, Following Splenectomy in Banti's Disease.—Dr. John E. Summers of Omaha reported a case in which he did a splenectomy. Later there developed symptoms of acute perforative appendicitis for which the abdomen was opened. Recovery finally took place. From the conditions of the case it was concluded that the postoperative thrombosis of the splenic vein which was observed could be considered only as due to the traumatism of splenectomy. No case of edema with gangrene of the large intestine following splenectomy had been noted by the author in literature nor did he recall any cases of gangrene of the large intestine the result of thrombosis of the superior mesenteric artery or vein.

Carcinoma of the Appendix, with Metastases to the Ileocolic Glands.—Dr. Robert G. LeConte of Philadelphia said that when carcinoma was confined to the appendix the removal of the appendix resulted in cure. He reported a case in which the disease had extended to the cecum with metastases to the ileocolic glands. Upon removal of the appendix it was found to be invaginated into the head of the cecum. The entire appendix was found to be the seat of carcinoma and the tumor growth had extended into the cecum. Subsequently the cecum with a portion of the ileum was resected with the entire group of ileocolic glands. Apparently perfect recovery followed.

Experiments in Flushing the Intestinal Canal with Salt Solution Through Enterotomy Openings.—Dr. George H. Monks of Boston reported the results of his studies on animals and human cadavers for the removal of intestinal contents by flushing the canal of the intestine through multiple enterotomy openings. He believed that in cases in which the life of a patient was in jeopardy, because of acute intestinal poisoning, and in which less radical means had been effective, a part of the intestinal contents might with advantage be removed by this method. One case was referred to in which this method had been successfully carried out.

Congenital Idiopathic Dilatation of the Colon (Hirschsprung's Disease.—Dr. J. M. T. Finney of Baltimore reported a case in which he had operated for this condition. While some ten theories of etiology had been advanced no one theory would explain every case. The diagnosis, differential diagnosis, the different aids to diagnosis, symptomatology, prognosis, and treatment were fully dealt with. One method of treatment was suggested by the author as probably applicable to a larger proportion of cases than any other hitherto suggested. The author had followed this in his own case. It consisted of a preliminary enterostomy followed some months later by a colocolostomy with finally the complete excision of the affected portion. The artificial anus should be left open until after the success of the preceding steps had been assured. It should then be closed under cocaine.

Dr. Leonard Freeman of Denver reported a case of a pronounced type of Hirschsprung's disease in which the patient had not had a movement of the bowels for three months. In the operation the large intestine was plicated and replicated and replicated again. Anastomosis or resection of the bowel was impossible. The patient subsequently did well. While this operation was not considered an appropriate one for the ordinary case it was approved of in the case reported.

Pelvic Abscess, with Special Reference to Rectal Drainage.—Dr. Archibald MacLaren of St. Paul advised vaginal section in the vast majority of cases of intraperitoneal collections of pus in women. Tubercular inflammations, whether from cellular tissue, appendages, uterus, or appendix formed the exception to this rule. In the pelvic abscesses observed in men, it was said that the fear of increasing the infection or of further contaminating the abscess cavity had hitherto prevented the man having the same chance as the woman. Fecal fistula was thought to be more likely to follow in cases in which the abscess opened itself because of its opening at the top. When opened by the surgeon drainage was perfect and fistula not probable. Dr. MacLaren had made it a rule always to give a woman the benefit of vaginal section and a man the advantage of placing a tube in the rectum. This plan of procedure had often been followed with surprisingly good results.

Officers.—The following officers for the ensuing year were elected:—*President*, Dr. C. B. G. De Nancrède, Ann Arbor; *Vice-Presidents*, Drs. A. G. Gerster, New York City, and Leonard Freeman, Denver; *Secretary*, Dr. Robert G. LeConte, Philadelphia; *Treasurer*, Dr. Charles A. Powers, Denver; *Recorder*, Dr. Richard H. Harte, Philadelphia. The next meeting of the Association will be held in Philadelphia.

Appendix Separate from the Colon.—J. T. Williams reports the case of a man of thirty years, admitted to the hospital after he had recovered from a third attack of appendicitis, which was of a very severe and dangerous nature. On opening the abdomen the appendix was easily found somewhat to the outer side and towards the back of the cecum, lying embedded in the mesoappendix, but quite reversed; that is to say, the tip was near the end of that viscus, the proximal end some 2¼ inches up by the side of the gut. On opening the appendix, the lumen at either end was completely occluded, the middle portion being occupied with a small mass of hardened fecal matter, which was quite inodorous. This condition must be comparatively rare. Williams further states that he has seen recorded in one of the medical encyclopedias the case of a man who spat up his appendix.—*British Medical Journal.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of Idaho.

April 7 and 8, 1908.

ANATOMY.

1. Into how many classes are the bones of the skeleton divided? Name the irregular bones.
2. Describe the internal saphenous vein from origin to termination.
3. Give name, origin, function, distribution and branches of the tenth cranial nerve.
4. Name the organs contained in the middle mediastinum.
5. Name the muscles that act during quiet inspiration.

HISTOLOGY.

1. Mention some special property possessed by each of the following chemical reagents rendering them individually useful in the examination of animal tissues: Acetic acid, potassium acetate, potassium hydrate, hydrochloric acid, osmic acid.
2. Describe fully the microscopical examination of fresh blood, and name some foreign elements that may be observed by this means.
3. Briefly describe the development of the human embryo from the segmentation of the vitellus to the third month of gestation.
4. What are ferments, toxins opsonins, aggressins? Define immunity, natural and acquired.
5. Give the histology of the mammary gland.

PHYSIOLOGY.

1-2. Name the digestive juices, the ferments contained in them, their action on food materials. Use the following table:

Digestive juices.	Ferments contained in them.	Action on food materials.

3. (*a*) Describe a normal heart. (*b*) What causes heart sounds?
4. (*a*) What is blood pressure? (*b*) Tabulate the physiological causes of alteration in blood pressure.

May be raised by——	May be lowered by ——

5. What changes occur in the blood in its passage through (*a*) the liver, (*b*) the spleen?
6. Describe the physiology of excretion of urine.
7. What effects are produced in the system by the removal of the thyroid gland?
8. (*a*) Describe deglutition. (*b*) What muscles are brought into action in swallowing?
9. (*a*) What is the function of the third cranial nerve? (*b*) What effect would the division of this nerve produce?
10. Describe the (*a*) splenic circulation, (*b*) portal circulation.

MATERIA MEDICA AND THERAPEUTICS.

1. What is the highest authority on materia medica in the United States? On what does its authority rest? How many official preparations are considered?
2. Mention five changes made in the eighth revision of the U. S. P.
3. Mention the drug you consider the best: General anesthetic, analgesic, mydriatic, expectorant, sternutatory, antisialic, refrigerant, carminative, anthelmintic, sudorific.
4. Mention relative dosage by mouth, rectum, and hypodermic administration.
5. Give the therapeutics of normal saline solution.
6. What is Basham's mixture? Dover's powder? Fowler's solution? Golden Seal? Peruvian bark? Salammoniac? Tartar emetic? Spirit of Mindererus? Paregoric? Sugar of lead?
7. What is sparteine? anilin? atrophine? bromine? caffeine, codeine, brucine, phenol, scopolamine? eserine?
8. Mention antidotes to opium, strychnine, aconite, silver nitrate, belladonna, carbolic acid, corrosive sublimate, iodine, phosphorus, chloroform.
9. Give preparation, dosage, physiological action, and therapeutics of colchicum.
10. Give preparation, dosage, physiological action, and therapeutics of nux vomica.

CHEMISTRY AND TOXICOLOGY.

1. What chemical elements are found in the human body?
2. What is a chemical compound? A chemical mixture? Give examples of each.
3. Hydrogen, oxygen, and nitrogen, describe each. Name some important compounds of each. How do they exist in nature?
4. Name and describe the three strong mineral acids. State how formed. Give properties and uses of each.
5. What are ptomains? toxins? proteins? nucleins?
6. Describe the symptoms of digitalis poisoning; give treatment.
7. State the differential diagnosis between poisoning by arsenic and mercury.
8. In a case of suspected homicidal poisoning what part of the cadaver should be preserved? How?
9. State the common courses of poisoning by lead. How treated?
10. Name five corrosive poisons; give treatment for each.

HYGIENE.

1. Describe sanitary measures for a dairy in an Idaho town.
2. What hygienic treatment for tuberculosis would you advise in Idaho?
3. Mention the dangers of the domestic use of "ditch water" in an irrigated country; dangers of the open well. How can a farmer secure the most wholesome water supply?
4. Mention five food poisons.
5. Give a list of five infective insects.
6. What are the three principal factors in hygienic living?
7. What climate is most favorable to a patient with tuberculosis? rheumatism? Bright's disease, chronic rhinitis and pharyngitis? chronic bronchitis? asthma? hay fever?
8-9-10. Describe the hygienic care of children under five years of age—food, clothing, bathing, play, and education.

DIAGNOSIS.

1. Give the differentiating points between smallpox and chickenpox.
2. Make a table differentiating chlorosis, progressive pernicious anemia, and leucocythemia.
3. With what may eczema be most frequently confounded? Give differential points.
4. Give the physical findings in the different stages of pneumonia.
5. Give the period of incubation of parotitis, pertussis, gonorrhea, syphilis, and measles.
6. More or less fever, dull pain in back, nausea and persistent vomiting at the beginning. Skin harsh and dry, pain from back to pudendum, urine scanty and high color, albuminous, high specific gravity with decrease of urea, contains epithelial casts and blood discs. What is the diagnosis?
7. Locate the valve areas of the heart.
8. What is Babinski's reflex? Describe Argyll-Robertson pupil. What are Koplik's spots? What is Kernig's sign?
9. Differentiate between appendicitis, gallstone colic, and renal colic.
10. Give five instances of referred pain, also locations and character of lesion producing each.

PATHOLOGY.

1. Locate the valves of the heart on the thoracic wall and describe the areas over which the murmurs may best be heard.
2. Define hernia; (*a*) direct; (*b*) indirect; (*c*) internal; (*d*) external; (*e*) what constitutes the lining of the hernial sac?
3. Give some causes of rupture or perforation of the esophagus.
4. What is the cause of prolapse of the rectum? At what age is it most frequent?
5. If called in a medico-legal case, where the complaint was vaccinated syphilis, how would you differentiate between the congenital and acquired lesions?
6. Give a descriptive definition of cretanism.
7. Diagnose a floating tumor in the abdomen by exclusion.
8. Define arteritis, arteriosclerosis, teratoma, opsonin, rhinoscleroma, morphology.
9. Give the pathological condition found in the different stages of croupous pneumonia.
10. Under what diseased condition would you find bacillus tuberculosis in the urine? How could you absolutely differentiate from the smegma bacillus?

THEORY AND PRACTICE.

1. Relapsing fever (febris recurrens). Define. Give the etiology and symptoms.
2. Variola. Define and give the etiology.

3. Diphtheria. Define and give the morbid anatomy.
4. Syphilis. Name the various ways of treating with hydrargyrum, and give the advantages and disadvantages of each.
5. Arthritis deformans. Give the etiology and treatment.
6. Diabetes insipidus. Give the etiology, symptoms, and treatment.
7. Intestinal obstruction. Name four causes.
8. Acute general peritonitis. Give the morbid anatomy.
9. Acute pleurisy. Give the physical signs and symptoms.
10. Aortic stenosis. Give the physical signs and differentiate from aortic regurgitation.

OBSTETRICS.

1. What treatment would you advise for a case of continued menstruation during pregnancy?
2. Name the source, character, relative quantity, and functions of the liquor amnii.
3. Describe the three stages of labor, and give the management of each stage.
4. (*a*) State the effects of anesthetics on the os uteri, abdominal muscles, perineum, and child. (*b*) Give the indications and contraindications for the employment of anesthetics during labor.
5. (*a*) Define caput succedaneum. (*b*) State how it is produced. (*c*) Where does the caput succedaneum appear in R. O. P.? in face presentations?
6. (*a*) What are the varieties of face presentation? (b) Give the diagnosis and treatment of each variety.
7. Give the varieties, causes, and treatment of hemorrhage in (*a*) the pregnant woman, (*b*) the parturient woman, (*c*) and the puerperal woman.
8. Describe your method for delivery of the aftercoming head in left-sacro-anterior position.
9. Give the etiology, symptoms, and treatment of phlegmasia alba dolens.
10. What are the symptoms and treatment of puerperal insanity?

GYNECOLOGY.

1. Menorrhagia and metrorrhagia. Define each. Give causes, both local and general, and symptoms.
2. Sterility. Name five causes.
3. Tuberculosis of the Fallopian tubes. Give pathological anatomy and diagnosis.
4. Vulvitis. Name three varieties and give the causes of two.
5. Hematoma of the vulva. Give causes and treatment.
6. Pudendal hernia. Describe fully. To what form of hernia does it correspond in the male?
7. Describe the anatomy of the uterus, ovaries, and tubes.
8. Uterine fibroids. Give pathology. Name three varieties and give treatment.
9. Acute oophoritis. Define. Give etiology, symptoms, and treatment.
10. Colpoperineorrhaphy (Hegar). What is the object of this operation? Describe the operation.

SURGERY.

1. Give in detail preparations for aseptic and antiseptic surgical operations. In all other questions omit the same in your answers.
2. Give minute directions for male catheterization, mentioning errors to be carefully avoided.
3. Give points of diagnosis, prognosis, and treatment of punctured wound of a joint, for instance, the knee joint.
4. Give treatment for acute osteomyelitis.
5. How would you treat fractured ribs?
6. Give differential diagnosis and treatment of dorsal dislocation of the thigh, and reason for each movement in reduction.
7. Describe in detail tracheotomy. Under what conditions would you employ it?
8. Give indications and counterindications for appendicectomy.
9. How detect a floating kidney? Describe required operation in detail.
10. Differentiate between benign and malignant tumors, and give general classification of each.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF IDAHO.

April 7 and 8, 1908.

ANATOMY.

1. The bones of the skeleton are divided into four classes:—Long, short, flat, and irregular bones. The irregular bones are:—The vertebræ, sacrum, coccyx, temporal, ethmoid, sphenoid, superior maxilla, inferior maxilla, malar, palate, inferior turbinate, and hyoid.
4. The middle mediastinum contains: The pericardium, heart, ascending aorta, lower part of superior vena cava, termination of vena azyos major, bifurcation of trachea, two bronchi, pulmonary artery, right and left pulmonary veins, phrenic nerves and their accompanying arteries, and some bronchial lymphatic glands.
5. The muscles that act during quiet inspiration, are: The Diaphragm, Scalenus anticus, Scalenus medius, Scalenus posticus, External intercostals, Internal intercostals, and Levatores costarum.

HISTOLOGY.

4. *Ferments* are microorganisms which by their presence and growth cause definite chemical changes in certain substances contained in the media in which they develop.

Toxins are poisonous substances produced by bacteria or other cells.

Opsonin is that quality of a serum which makes a microorganism more susceptible to phagocytosis.

Aggressins are chemical substances elaborated by pathogenic microorganisms, which substances are capable of acting upon the cells and fluids of the infected body and so overcome its resistance to infection.

Immunity is the power of resistance of cells and tissues to the action of pathogenic bacteria. Immunity may be either natural or acquired.

Natural Immunity is this power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired Immunity is this resistance acquired: (1) by a previous attack of the disease caused by the bacteria, or (2) by the person being made artificially insusceptible. The conditions which give immunity from the pathogenic action of bacteria are:—(1) a previous attack of the disease; (2) inoculation, with small quantities of bacteria, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

PHYSIOLOGY.

1. 2.

Digestive juices.	Ferments contained in them.	Action on food materials.
Saliva.....	Ptyalin.	Changes starches into dextrin and sugar.
Gastric Juice...	Pepsin.	Changes proteids into proteoses and peptones in an acid medium.
	A curdling ferment.	Curdles the casein of milk.
Pancreatic Juice	Trypsin.	Changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; in an alkaline medium.
	Amylopsin.	Converts starches into maltose.
	Steapsin.	Emulsifies and saponifies fats.
	A curdling ferment.	Curdles the casein of milk.
Intestinal Juice.	Invertin.	Converts maltose into glucose.

3. (*b*) The causes producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

4. (*a*) Blood pressure is the pressure on the blood due to the ventricular systole, the elasticity of the walls of the arteries, and the resistance of the capillaries.

(*b*) Blood pressure:—

May be raised by—	May be lowered by—
1. By the heart beating more quickly.	1. By the heart beating more slowly.
2. By the heart beating more powerfully.	2. By the heart beating more feebly.
3. By contraction of the arterioles.	3. By dilatation of the arterioles.
	4. By deficient supply of blood to the left ventricle.

5. (*a*) In its passage through the liver, the blood loses plasma, fat, proteids, organic matter; it gains sugar, urea, and heat; and it becomes less coagulable.

(*b*) In its passage through the *Spleen*, some say that the blood loses corpuscles, and others say that it gains corpuscles.

7. Removal of the thyroid gland causes mental and bodily dullness and apathy, tremors, twitchings, overgrowth of the connective tissues, and development of fat; the hairs fall out, and the patient becomes unwieldy and clumsy in both body and mind. Complete removal causes death in most animals, and it is not considered justifiable in man.

8. (*b*) The muscles brought into action in swallowing, are: The hyoglossi, styloglossi, palatoglossi, palatopharyngei, azygos uvulæ, tensores palati, levatores palati, stylopharyngei, stylohyoids, geniohyoids, mylohyoids, thyrohyoids, digastrics, constrictors of the pharynx, and the muscles of the tongue.

9. (*a*) The third cranial nerve is the motor nerve to all the muscles of the orbit except the Superior oblique and the External rectus. Hence, it supplies the Rectus superior, Rectus inferior, Rectus internus, Inferior oblique, and Levator palpebræ superioris. It also (through the ciliary ganglion) supplies the sphincter muscle of the iris, and the ciliary muscle.

(*b*) Division of this nerve would produce: Ptosis of the upper lid, external strabismus, slight prominence of the eyeball, dilatation of the pupil, and loss of the power of accommodation.

MATERIA MEDICA AND THERAPEUTICS.

1. The highest authority on Materia Medica in the United States is the United States Pharmacopœia.

Its authority rests on the Medical Profession; it has not the force of law.

The number of official preparations considered in the United States Pharmacopœia, is 415.

2. Five changes made in the eighth revision of the U.S.P.: (1) Tincture of aconite was reduced in strength from 35 per cent. to 10 per cent. (2) Tincture of veratrum was reduced in strength from 40 per cent. to 10 per cent. (3) Catechu is replaced by Gambir. (4) The name Phenol is substituted for Carbolic Acid. (5) Sulphur ointment was reduced from 30 per cent. to 15 percent.

3. *General anesthetic*, Ether. *Analgesic*, Opium. *Mydriatic*, Homatropine. *Expectorant*, Ipecacuanha. *Sternutatory*, Tobacco. *Antisialic*, Atropine. *Refrigerant*, Cold water. *Carminative*, Cardamom. *Anthelmintic*, Santonin. *Sudorific*, Pilocarpus.

4. As a general rule, the relative dosage by mouth, rectum, and hypodermic administration would be 1:2:½.

6.

Basham's Mixture	Liquor Ferri et Ammonii Acetatis.
Dover's Powder	Pulvis Ipecacuanhæ et Opii.
Fowler's Solution	Liquor Potassii Arsenitis.
Golden Seal	Hydrastis.
Peruvian Bark	Cinchona.
Salammoniac	Ammonii Chloridum.
Tartar Emetic	Antimonii et Potassii Tartras.
Spirit of Mindererus	Liquor Ammonii Acetatis.
Paregoric	Tinctura Opii Camphorata.
Sugar of Lead	Plumbi Acetas.

7.

Sparteine	Alkaloid of Scoparius.
Anilin	Phenyl amine; a coal tar derivative.
Atropine	Alkaloid of Belladonna.
Bromine	An element; one of the Halogens.
Caffeine	Alkaloid of Caffea Arabica.
Codeine	Alkaloid of Opium.
Brucine	Alkaloid of Strychnos nux vomica.
Phenol	Phenyl hydroxide; formerly Carbolic Acid.
Scopolamine	Alkaloid of Scopola atropoides.
Eserine	Alkaloid of Physostigma.

8.

	ANTIDOTES.
Opium	Strychnine. Amyl nitrite.
Strychnine	Chloral or Chloroform.
Aconite	Digitalis, and Stimulants.
Silver Nitrate	Salt and water.
Belladonna	Stimulants. Pilocarpine.
Carbolic Acid	Magnesium Sulphate. Alcohol.
Corrosive Sublimate	White of egg followed by Emetic.
Iodine	Starch.
Phosphorus	Old French oil of Turpentine; Copper sulphate, potassium permanganate.
Chloroform	Artificial respiration. Amyl nitrite.

CHEMISTRY AND TOXICOLOGY.

1. The chemical elements found in the human body are: Hydrogen, oxygen, carbon, nitrogen, sulphur, phosphorus, chlorine, calcium, sodium, potassium, magnesium, lithium, iron, silicon, and fluorine.

2. *A chemical compound* is a substance made up of two or more elements, chemically united, in definite proportions. Examples: water, sulphuric acid, iodoform.

A mixture is the product obtained by uniting into a more or less homogeneous whole two or more substances, whether elements or compounds, in any proportion, and without any chemical union. Examples: air, sugar adulterated with sand, salt in water.

3. Hydrogen is a colorless, odorless, tasteless gas, the lightest known substance; it has a great affinity for oxygen; it supports neither combustion nor respiration; it is a necessary constituent of all acids; the gas will burn with a pale blue flame, giving little light, but an intense heat.

Some important compounds: Water, hydrogen dioxide, all acids.

Occurrence: free in volcanic gases, in fire damp, and the gases of the intestines; and in combination in water, in all acids and in many organic compounds.

Oxygen is a colorless, odorless, tasteless gas, heavier than air, slightly soluble in water, has an intense affinity for other elements, combining with almost all of them except fluorine. It is necessary to life, and is a supporter of combustion.

Some important compounds: Water, potassium permanganate, all oxides, and all oxyacids.

Occurrence: free in the air and in combination in water, rocks, minerals, etc. It is more abundant than any other element, forming about forty per cent. of the total weight of the earth.

Nitrogen is a colorless, odorless, tasteless gas, it neither burns nor supports combustion nor respiration, it has no tendency to unite with other elements.

Some important compounds: Ammonia, nitric acid, urea, nitrogen monoxide.

Occurrence: free in the air, in combination in nitrates, ammonia, and in many organic substances.

4. The three strong mineral acids: (1) *Hydrochloric acid.* It is *formed* by the action of sulphuric acid upon sodium chloride:

$$H_2SO_4+2NaCl=Na_2SO_4+2HCl$$

Properties. When pure this is a colorless gas with a sharp, penetrating, and irritating odor; it is very soluble in water; it does not support combustion nor does it burn in air; it is very corrosive. The ordinary hydrochloric acid is a solution of this gas in water, and is found in three varieties: the commercial, the pure, and the dilute acids.

Uses. For bleaching, disinfecting; and for manufacturing and chemical purposes.

(2) *Sulphuric acid.* It is *formed* by oxidizing sulphur dioxide in the presence of water:

$$2SO_2+2H_2O+O_2=2H_2SO_4$$

Properties. It is a colorless, thick, oily liquid, odorless, very corrosive; has a great tendency to unite with water; it chars organic matter.

Uses. For manufacturing and chemical purposes.

(3) *Nitric Acid.* It is *formed* by the action of sulphuric acid upon potassium nitrate:

$$H_2SO_4+KNO_3=KHSO_4+HNO_3$$

Properties. It is a colorless or faintly yellow liquid, has a sour taste, a suffocating odor, and is very corrosive. It is a strong oxidizing agent, and stains animal tissues yellow.

Uses. For chemical purposes, and as an oxidizing agent.

5. *Ptomaines* are basic, nitrogenous compounds, produced from protein material by the bacteria which cause putrefaction.

Toxins are the poisonous products of bacteria.

Proteins are substances of unknown constitution which are indispensable to all animal and vegetable life. They are composed of carbon, hydrogen, oxygen, and nitrogen; some also contain sulphur and phosphorus.

Nucleins are the residues of the nucleo-proteids after peptic digestion. They contain phosphorus.

6. *Symptoms of Poisoning by Digitalis:* "Nausea, and occasionally vomiting. Sometimes colic and diarrhea. After two or three hours, marked diminution in the frequency of the pulse, which may fall to 40 or even 25. Dyspnea, attended by a sense of oppression in the chest and coldness of the extremities. Headache, vertigo, and tendency to sleep. Usually attacks of syncope occur, provoked sometimes by the slightest movement of the patient. Death is generally by syncope, sometimes after several hours of coma succeeded by convulsions.

"*Treatment:* The patient must be kept strictly in the recumbent position. The stomach should be washed out with infusion of tea by the stomach tube. Stimulants should be given."—(Witthaus's *Essentials of Chemistry.*)

7.

Poisoning by Arsenic.	Poisoning by Mercury.
(1) The symptoms rarely begin within 20 minutes.	(1) The symptoms begin almost immediately.
(2) Pain is usually limited to the stomach and throat.	(2) Pain is also severe in the mouth.
(3) The taste is very faint, sweetish and metallic. Usually none.	(3) The taste is intensely metallic, and nauseous.
(4) The mouth and tongue are normal.	(4) The mouth and tongue are whitened.
(5) The urine contains arsenic.	(5) The urine contains mercury.

(Witthaus' *Essentials of Chemistry.*)

8. In case of suspected homicidal poisoning, the following parts of the cadaver should be preserved:—"The alimentary canal from the cardia to the middle of the rectum, *unopened*, and the contents enclosed by ligatures at the esophagus, duodenum, and lower end of gut; the liver, including the gall-bladder; one kidney; the spleen; a piece of muscular tissue from the leg; the brain, and any urine which may remain in the bladder.

"They are to be placed in *clean* and *new* glass jars, closed with glass or cork covers or stoppers. Jars with metallic caps should never be used. Tapes or cords should be tied about the jar and cap, to which they should be attached by sealing wax bearing impressions of a seal, in such a manner that access can only be had to the interior after breaking the seals or cutting the tapes or cords. Great care must be exercised that no sealing-wax can get into the jars. Each portion should be placed in a jar by itself." (Witthaus' *Essentials of Chemistry.*)

9. The most *common sources of lead poisoning* are the following:

"The contamination of drinking water from lead pipes. Contamination of articles of food or drugs by contact with leaden vessels, or from being enclosed in tinfoil containing an excess of lead. Drinking beer, cider, etc., which has been drawn through leaden pipes or allowed to stand in pewter vessels. The ingestion or constant handling of lead or its compounds, as the acetate, nitrate, carbonate (white lead—painter's colic), Goulard's extract, etc. The use of hair dyes containing lead."

The *treatment* consists in removing the cause and administering the antidote, "magnesium sulphate, which brings about the formation of the insoluble lead sulphate, while the purgative action of the magnesia is also useful. It should be preceded by an emetic, or by the use of the stomach tube." (Witthaus' *Essentials of Chemistry.*)

10. Five corrosive poisons, with treatment:

(1) Corrosive Sublimate: Give white of egg, in not too great a quantity, and follow it with an emetic.

(2) Carbolic Acid: Give white of egg, or sodium sulphate, and gently wash out the stomach.

(3) Sulphuric Acid: Give magnesia, suspended in water, or a strong solution of soap.

(4) Potassium hydroxide (Potash): Give vinegar.

(5) Oxalic Acid: Give slaked lime suspended in a small quantity of water, follow with an emetic.

In all cases of corrosive poisoning avoid the use of stomach pump or tube.

HYGIENE.

4. Five food poisons: (1) Sausage poisoning (Allantiasis, Botulism). (2) Meat poisoning. (3) Poisonous fish. (4) Poisonous shell fish. (5) Poisonous cheese (tryotoxicon), milk, etc.

5. Five infective insects: Tsetse fly, mosquitos, flies, ticks, fleas.

6. Three principal factors in hygienic living: Pure air, pure water, and sunlight.

7. The following notes on climate are from the *Reference Handbook of the Medical Sciences. Tuberculosis*: The essential climatic conditions are pure air free from dust, protection from high winds, moderate dryness and equability, and a dry soil. With it must be associated the most careful, continuous, medical supervision. Assuming that the patient is in the incipient, curable stage, and that there are no other contraindicating conditions, the favorable climates are: (*a*) High altitudes, like Colorado, New Mexico, the Alps; (*b*) low altitudes, like the Adirondacks, Asheville, the Southern Pine Belt, and Southern California; (*c*) coast climates, represented by the Riviera resorts; (*d*) island climates, like Madeira and the Canaries; (*e*) ocean voyages.

Rheumatism: Warmth, dryness, equability, and sunshine are essential factors in the climatic treatment of rheumatism; such conditions are found in Texas, Arizona, the Southern Pine Belt, some portions of southern California, the inland Florida resorts, the desert of Egypt, and Algeria. The hydrotherapeutic treatment of this disease as exhibited at such resorts as Richfield Springs, the Virginia Hot Springs, the Arkansas Hot Springs, Aix-les-Bains, and others, is most efficacious.

Bright's Disease: A warm, equable, windless climate, such as is found in many low inland or coast resorts, examples of which are Arizona, Madeira, the Southern Pine Belt, Florida, Southern California, etc. The West Indies are highly extolled by Burney Yeo.

Chronic Bronchitis: When expectoration is abundant, a dry, warm, inland climate like Thomasville, Augusta, Summerville, and Camden, S. C., southern California, in the winter; and the seaside or mountains in the summer. If the expectoration is scanty, a warm moist climate like Florida, Nassau, Algiers, Madeira, in winter; and Newport, the Jersey Coast, Nantucket, Cape Cod, etc., in the summer.

Asthma: The high-altitude resorts appear to give the best results, especially when the neurotic element seems to be the prominent factor in the case. If the bronchitis seems to be the most important element, either a sedative or a stimulant climate is to be selected according to the character of the bronchitis. Or if the exciting cause appears to be the most important, especial consideration must be given to that in the selection of a resort.

Hay Fever (*Nasal Asthma*): The Adirondacks, White, Catskill, and Alleghany Mountains, Mackinac Island, Georgian Bay, Cape Breton, the "North Woods," Beach Haven, Fire Island, and Halifax, Nova Scotia, are some of the many resorts which afford more or less immunity. An ocean voyage and traveling in Europe are also prophylactic.

DIAGNOSIS.

1. Differentiation between smallpox and chickenpox: (1) Very young children are attacked with varicella, whereas variola usually shows itself in adults. (2) Vaccinated children readily take varicella; not so variola, even in the modified form. (3) Children who have had varicella may contract variola, even soon afterwards; or the two diseases may coexist. (4) Varicella is noninoculable, whereas variola is notoriously so. (5) The eruption of varicella appears in twenty-four hours; that of variola not till the third day. (6) The febrile symptoms continue after the eruption appears in varicella; those of variola subside. (7) In varicella the spots come out in successive crops; this is never seen in variola. (8) The spots in varicella are unilocular, and collapse on being punctured; the spots in variola are multilocular, and do not collapse on being punctured. (9) In varicella the eruption is very irregular, and appears over the body generally; in variola it appears in groups of threes and fives, and is always seen on the limbs. (10) The papule in varicella is soft, and disappears on stretching the skin; in variola it is hard and shotty, and does not disappear on stretching the skin. (From J. W. Moore's work on *Variola and Varicella.*)

2. The following table is compiled from one in Butler's *Diagnostics of Internal Medicine*:

Chlorosis	Progressive Pernicious Anemia	Leucocythemia	
		Spleno-Myelogenous	Lymphatic
Red cells average 4,000,000; rarely under 2,000,000. Poikilocytosis. Many microcytes. Occasional normoblasts.	*Red cells* average 1,000,000. Microcytes, megalocytes. Normoblasts moderately numerous. Megaloblasts present, often exceed normoblasts.	*Red cells*, about 3,000,000; rarely under 2,000,000. Numerous normoblasts. Megaloblasts moderately numerous. Some gigantoblasts.	*Red cells* about 3,000,000 or somewhat less. Normoblasts and megaloblts comparatively rare
Hemoglobin always relatively low.	*Hemoglobin* often relatively high.	*Hemoglobin* normal or relatively decreased.	*Hemoglobin* diminished.
White cells normal or slightly increased.	*White cells* usually decreased.	*White cells* average 450,000. Maybe 1:10, 1:5 or 1:1 red.	*White cells* average 100,000 or less.
Lymphocytes increased.	*Lymphocytes* increased.	*Lymphocytes* 7.5%.	*Lymphocytes* 90%.
Polynuclears decreased.	*Polynuclears* decreased.	*Polynuclears* 49%.	*Polynuclears* 3%.
Eosinophiles normal.	*Eosinophiles* normal.	*Eosinophiles* 4.5%.	*Eosinophiles* 0.7%.
Myelocytes rare.	*Myelocytes* common; usually eosinophilic.	*Myelocytes* 35%	*Myelocytes* 0.3%.

6. Acute nephritis.

7. See below, Pathology, Question 1.

8. *Babinski's reflex*: When the sole of the foot is tickled, the toes extend instead of flex.

Argyll-Robertson pupil is the condition of the pupil in which it responds to accommodation, but not to light.

Koplik's spots: Small red spots with a bluish-white center, found on the inner surface of the cheeks in measles; it is evident before the eruption appears on the skin.

Kernig's sign: With the patient in the dorsal position, and the thigh flexed at right angles to the pelvis, there is inability to straighten the leg completely. The condition is found in meningitis.

10. *Five instances of referred pain*: (1) Pain on the inner surface of the knee in hip joint disease. (2) Pain in the mammary gland in uterine disease. (3) Pain over the region of the stomach in caries of the spine. (4) Pain in the penis or testicle in stone in the kidney. (5) Pain under the right scapula in hepatic disorders.

PATHOLOGY.

1. *Location of the valves of the heart on the thoracic wall*: "The *right auriculo-ventricular valves* are situated behind the sternum above the level of the fourth costal cartilage; the *left auriculo-ventricular valves* are opposite the third intercostal space, about one inch to the left of the sternum; the cusps of these valves extend as low as the fifth costal cartilage. The *pulmonary valves* lie immediately behind the junction of the third left costal cartilage with the sternum; the *aortic valves* are behind the upper border of the third intercostal space just at the left side of the sternum." (Holden.)

The *mitral* murmurs may be best heard at the apex of the heart, in the left fifth intercostal space, near the nipple. The *aortic murmurs* may be best heard in the second right intercostal space, near the sternum. The *pulmonary* murmurs may be best heard in the second left intercostal space, near the sternum. The *tricuspid* murmurs may be best heard on the left border of the sternum near the ensiform cartilage.

2. *Hernia* is the protrusion of a viscus from its normal situation through an opening in one or more of the layers forming the wall of the cavity within which it is contained.

(*a*) A *direct* (inguinal) hernia, is one passing directly through the external abdominal ring without having passed through the inguinal canal.

(*b*) An *indirect* (inguinal) hernia is one that passes through the inguinal canal before appearing at the external abdominal ring.

(*c*) An *internal* hernia is the protrusion of a viscus through an aperture in the interior of the body.

(*d*) An *external* hernia is one that protrudes through an opening in the wall of a cavity.

(*e*) The hernial sac is lined with peritoneum.

3. *Causes of rupture or perforation of the esophagus*: Excessive vomiting or retching, particularly after the ingestion of large quantities of food or drink; carcinoma; abscess; aneurysm; foreign bodies.

4. *Cause of prolapse of the rectum*: Relaxation of the tissues due to excessive straining, and debility. It is most frequent in childhood.

5. A hoarse cry, coryza, labial fissures, protruding forehead, "sniffles," and the "syphilitic facies" would all indicate the congenital rather than the acquired variety of syphilis.

6. "Cretinism is a condition characterized by an arrest of mental and physical growth, and associated with hypoplasia or absence of the thyroid. It usually arises in the early years of life, but is occasionally congenital. The cretin is stunted, the lips thick, the skin dry and rough, the abdomen large, and the genitals remain infantile, and the mental state is that of an imbecile." (Hewlett's *Pathology.*)

8. *Arteritis* is inflammation of one or more coats of an artery.

Arteriosclerosis is a degenerative process of the intima of an artery.

Teratoma is a congenital tumor containing fetal remains; it is supposed to be due to an abortive fetus being included in another fetus, which latter develops normally.

Opsonin is that quality of a serum which makes a microorganism more susceptible to phagocytosis.

Rhinoscleroma is an indurated new growth of the skin and mucous membrane of the nose.

Morphology is that branch of science which treats of the form and structure of organized beings, and of variations in such form and structure.

10. Tubercle bacilli are found in the urine in tuberculous diseases of the urinary tract.

To differentiate the tubercle bacillus from the smegma bacillus: After treating the film with the dilute mineral acid, dip it in absolute alcohol for one or two minutes; the smegma bacillus will be decolorized, whereas the tubercle bacillus will not be decolorized.

THEORY AND PRACTICE.

4. The various ways of treating syphilis with hydrargyrum, and their advantages and disadvantages, are:

Method.	Advantages.	Disadvantages.
By mouth.	Simple, easy, dosage easily regulated.	May upset digestion.
Fumigation.	Rapid effect. Psychic effect.	Troublesome, special devices or apparatus required.
Inunction.	Efficient. Does not disturb digestion. Useful, to give stomach a temporary rest.	Uncleanly.
Hypodermic injection.	Effective, rapid, does not disturb digestion.	Painful. Abscess formation. Requires attendance of physician for every dose.
Intravenous injection.		Dangerous.

OBSTETRICS.

1. Rest in bed is the only treatment required for continued menstruation during pregnancy; but the condition is rare, and one should suspect ectopic gestation, placenta prævia, or abortion.

2. The liquor amnii is the fluid contained in the amniotic sac; it is alkaline in reaction, has a specific gravity of about 1.001 to 1.008, its quantity is variable, but is generally about two pints. It consists chiefly of water, but contains small amounts of albumin, epithelial cells, urea, phosphates, chlorides, etc. Its source is unsettled.

Functions: (*a*) *During Pregnancy*: (1) As a protection to the fetus against pressure and shocks from without. (2) As a protection to the uterus from excessive fetal movements. (3) It distends the uterus, and thus allows for the growth and movements of the fetus. (4) It receives the excretions of the fetus. (5) It surrounds the fetus with a medium of equable temperature, and serves to prevent loss of heat. (6) It prevents the formation of adhesions between the fetus and the walls of the amniotic sac. (7) It has been supposed, by some, to afford some slight nutrition to the fetus.

(*b*) *During Labor*: It acts as a fluid wedge, and dilates the os uteri and the cervix; it also slightly lubricates the parts.

7. The following (from Gould and Pyle's *Cyclopedia of Medicine and Surgery*) is a useful classification of the hemorrhages in question:

A. Hemorrhages of Pregnancy: Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) appoplexy of the decidua or placenta.

B. Hemorrhages of Labor: Caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) relaxation of the uterus; (4) laceration of the cervix; (5) rupture or inversion of the uterus.

C. Hemorrhages of the Puerperium: Caused by (1) retained secundines; (2) displaced uterus; (3) displaced thrombi; (4) fibroid tumors; (5) hypertrophied decidua; (6) carcinoma.

GYNECOLOGY.

1. *Menorrhagia* is an excessive loss of blood at the menstrual periods.

Metrorrhagia is a hemorrhage from the uterus at other than the menstrual periods.

Local causes: Uterine displacements, malignant disease, inflammations of uterus or appendages, fibroids, cystic degeneration of the cervix, subinvolution, ectopic gestation, abdominal tumors.

General causes: Hemophilia, scurvy, purpura, malaria, anemia, mitral disease, diseases of kidneys, or liver, acute infectious fevers.

Symptoms: The hemorrhage at or between the menstrual periods is the characteristic symptom.

2. *Five causes of sterility*: (1) Absence or lack of development of any part of the genital tract; (2) gonorrhea; (3) pronounced flexions of the uterus; (4) salpingitis; (5) great obesity.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	July 7
Arizona*	Ancil Martin, Phoenix	Phoenix	July 6
Arkansas*	F. T. Murphy, Brinkley	Little Rock	July 14
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	August 4
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	July 7
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	July 14
Delaware	J. H. Wilson, Dover	Dover	Dec. 8
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	July 14
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	Nov. 11
Georgia	E. R. Anthony, Griffin	Atlanta	Oct. 6
Idaho	W. F. Howard, Pocatello	Boise	Oct. 6
Illinois	J. A. Egan, Springfield	Chicago	July 22
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis	Oct. 27
Iowa	Louis A. Thomas, Des Moines	Des Moines	Sept. —
Kansas	D. P. Cook, Clay Center	Kansas City	Oct. 13
Kentucky*	J. N. McCormack, Bowling Green	Louisville	July 7
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	Oct. 1
Maine	Wm. J. Maybury, Saco	Augusta	July 7
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 8
Massachusetts*	E. B. Harvey, State House, Boston	Boston	July 14
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Lansing	Oct. 13
Minnesota	W. S. Fullerton, St. Paul	St. Paul	Oct. 6
Mississippi	S. H. McLean, Jackson	Jackson	Oct. 13
Missouri	J. A. B. Adcock, Warrensburg	Kansas City	Nov. 23
Montana*	Wm. C. Riddell, Helena	Helena	Oct. 6
Nebraska	E. J. C. Sward, Oakland	Lincoln	Aug. 5
Nevada	S. L. Lee, Carson City	Carson City	Nov. 2
N. Hampshire*	Henry C. Morrison, State Library Concord	Concord	July 15
New Jersey	J. W. Bennett, Long Branch	Trenton	Oct. 20

Virginia	R. S. Martin, Stuart	Richmond	
Washington*	C. W. Sharples, Seattle	Seattle	July 7
W. Virginia	H. A. Barbee, Point Pleasant	Charleston	July 14
Wisconsin	J. V. Stevens, Jefferson	Madison	July 14
Wyoming	S. B. Miller, Laramie	Cheyenne	

* No Reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Diplomas.—The following States do not require a diploma: Alabama, Arkansas, Colorado, Massachusetts, Mississippi, Rhode Island, and Tennessee.

Limited Reciprocity.—The following States reciprocate only on the basis of a written examination: Colorado, Delaware, District of Columbia, Illinois, New Hampshire, New York, North Dakota, Texas, and Wyoming.

Illinois.—At a special meeting of the Illinois State Board of Health, held April 5, the board, by a formal resolution, approved of the proposition to subject all physician applicants for a State license to a practical examination covering one day, in addition to the written examination, which requires three days for completion.

South Carolina.—The medical practice act of this State has been amended, as follows: The State Board of Medical Examiners is authorized to revoke licenses for just cause; the "five-year clause," which exempted physicians of five years' standing from examination has been eliminated; osteopaths may take the examination, but are excused the surgery and materia medica, therapeutics, and practice papers.

South Carolina recognizes reciprocity with the following States: Kansas, Maine, Maryland, Michigan, Minnesota, Missouri, Nevada, Texas, Utah, Virginia, West Virginia, Wisconsin, and Wyoming.

Opium Dealers in China.—According to a press dispatch from Shanghai, the Chinese opium sellers have been drawing lots among themselves to decide which of them shall close on July 1, according to the resolution passed by the taxpayers on March 21. It is understood that all of the shops will be closed by the end of the year.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending June 27, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	406	168
Diphtheria	286	28
Measles	658	19
Scarlet Fever	360	30
Smallpox	..	—
Varicella	116	—
Typhoid Fever	58	7
Whooping Cough	17	4
Cerebrospinal Meningitis	3	2
Malarial Fever	—	—
Totals	1904	258

Health Report.—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending June 26, 1908:

SMALLPOX—UNITED STATES.

THE CONQUEST OF THE VENEREAL DISEASES.*

By HAVELOCK ELLIS, M.D.,

LONDON, ENGLAND.

The immense damage done by syphilis and gonorrhea—by multiplying disease and abbreviating life, by causing sterility and blindness, as well as the parasyphilitic affection of general paralysis and tabes dorsalis, by deteriorating both the present and future generations, and at the same time inflicting an enormous pecuniary tax on every civilized community—is now all too familiar to need emphasis. The recognition of it is ancient, and was the chief cause of the establishment of police methods of regulating prostitution; for prostitution being the focus of venereal disease, it was supposed possible to stamp out venereal disease among prostitutes, and so suppress it altogether.

That view is no longer held save by a few ancient authorities whose careers have been too closely identified with systems of police regulations to allow of their changing their beliefs in old age. If there is any one conclusion which emerges from the conflicting discussions of this matter at the Brussels Conference of 1899, and subsequently, it is that all the old systems of interference and of non-interference with the venereal aspects of prostitution are unsatisfactory. Brothels are no longer the chief factor in prostitution, the character of prostitution is changing and the methods of dealing with venereal disease must change. The future, it is now beginning to be felt, belongs neither to the police regulation of prostitution, nor to *laissez-faire* indifference, but to the general sanitary control of disease on the basis of the common law.

The growing objection to police regulation may be traced equally in scientific opinion and in popular feeling. In France and elsewhere the municipalities of some of the largest cities have either suppressed the system of regulation entirely or shown their disapproval of it. In Germany, where there is in some respects more patient endurance of interference with the liberty of the individual than in France, England, or America, various elaborate systems of organizing prostitution and dealing with venereal disease continue to be maintained, but they cannot be completely carried out, and it is generally admitted that in any case they could not accomplish the objects sought.* The recent abandonment by Denmark of the police system in favor of a medical and sanitary system is a significant sign of the times.

"The struggle against syphilis is only possible if we agree to regard its victims as unfortunate and not as guilty. We must give up the prejudice which has led to the creation of the term 'shameful diseases,' and which commands silence concerning this scourge of the family and of humanity." In these words of Duclaux, the successor of Pasteur at the Pasteur Institute, in his noble and admirable book, "L'Hygiène Sociale," we have indicated to us, I am convinced, the only road by which we can approach the rational and successful treatment of the great social problem of venereal disease.

No evils can be combated until they are recognized and discussed. It is a significant and even symbolic fact that the bacteria of disease rarely flourish when they are open to the free currents of pure air. Obscurity and concealment furnish the best conditions for their vigor and diffusion, and these favoring conditions we have for centuries past accorded to venereal diseases. It was not always so, as, indeed, the survival of the word "venereal" in this connection, with its reference to a goddess, alone suffices to show. Even the name "syphilis" itself, taken from the romantic poem in which Fracastorus sought a mythological origin for the disease, bears witness to the same fact. The romantic attitude is indeed as much out of date as that of hypocritical and shame-faced obscurantism. We need to face these diseases in the same simple, direct, and courageous way which has already been adopted successfully in the case of smallpox.

At this point indeed we encounter those who say that it is unnecessary to show any sort of recognition of venereal diseases, and immoral to do anything that might seem to involve indulgence to those who suffer from such diseases; they have got what they deserve and may well be left to perish. Those who take this attitude place themselves so far outside the pale of civilization—to say nothing of morality or religion—that they might well be disregarded. The progress of the race, the development of humanity, in fact and in feeling, has consisted in the elimination of an attitude which it is an insult to primitive peoples to term savage. Yet it is an attitude which should not be ignored, for it still carries weight with many who are too weak to withstand those who juggle with fine moral phrases. I have even seen in a medical quarter the statement that venereal disease cannot be put on the same level with other infectious diseases because it is "the result of voluntary actions." But all diseases, indeed all the accidents and misfortunes of suffering human beings, are equally the involuntary results of voluntary actions. The man who is run over in crossing the street, the family poisoned by unwholesome food, the mother who catches the disease of the child she is nursing—all these suffer as the involuntary result of the voluntary act of gratifying some fundamental human instinct—the instinct of activity, the instinct of nutrition, the instinct of affection. The instinct of sex is as fundamental as any of these, and the involuntary evils

*Read before the Chicago Women's Medical Club.

*An interesting personal investigation of German methods was lately made by F. Bierhoff, "Police Methods for the Sanitary Control of Prostitution," *New York Medical Journal*, Aug., 1907.

which may follow the voluntary act of gratifying it stand on exactly the same level. This is the essential and fundamental fact: a human being in following the human instincts implanted within him has stumbled and fallen. Any person who sees, not this essential fact but merely some subsidiary aspect of it, reveals that his mind is twisted and perverted, and he has no claim to arrest our attention.

Even when we have put aside the vast number of venereally infected people who are in the narrowest and most conventionally moral sense, "innocent" victims of the syphilis or gonorrhea they have contracted, there is still much to be said. The majority of those who contract venereal diseases by illegitimate sexual intercourse are young. They are youths, ignorant of life, scarcely yet escaped from home, or they are young girls, who have indeed ceased to be absolutely chaste, but have not yet lost all their innocence, and who do not consider themselves, and are not by others considered, prostitutes; that indeed is one of the rocks on which the system of police regulation of prostitution comes to grief, for the police cannot catch the prostitute at a sufficiently early age. Of women in France who become syphilitic, according to Fournier, twenty to forty per cent. are infected before they are nineteen; and among men, fifteen per cent. of the cases occur between eleven and twenty-one years of age. In Germany Erb finds that as many as 85 per cent. of men with gonorrhea contracted the disease between the ages of sixteen and twenty-five. These young things for the most part fell into a trap which Nature had baited with her most fascinating lure; they were usually ignorant; not seldom they were deceived by an attractive personality, often they were overcome by passion; frequently all prudence and reserve had been lost in the fumes of wine. From a truly moral point of view they were scarcely less innocent than children.

"I ask," says Duclaux, "whether when a young man and a young girl abandon themselves to a dangerous caress society has done what it can to warn them. Perhaps its intentions were good. but when the need came for precise knowledge a silly prudery has held it back and it has left its children without viaticum. I will go further and proclaim that in a large number of cases the husbands who contaminate their wives are innocent. No one is responsible for the evil which he commits without knowing it and without willing it." The majority of husbands who infect their wives it has been found contracted the disease before marriage. They entered on marriage believing that their disease was cured and that they had broken with their past. Physicians have sometimes (and quacks frequently) contributed to this result by too sanguine an estimate of the period necessary to destroy the poison.

Even those who may be unwilling to abandon an attitude of private moral intolerance towards the victims of venereal disease may still do well to remember that, since the public manifestation of their intolerance is mischievous, and at the best useless, it is necessary for them to restrain it in the interests of society. They would not be less free to order their own personal conduct in the strictest accordance with their superior moral rigidity; and that after all is for them the main thing. But for the sake of society it is necessary for them to adopt what they may consider the convention of a purely hygienic attitude towards these diseases. The erring are inevitably frightened by an attitude of moral reprobation into methods of concealment, and these produce an endless chain of social evils which can only be dissipated by openness. As Duclaux has so earnestly insisted, it is impossible to grapple successfully with venereal diease unless we consent not to introduce our prejudices, or even our morals and religion, into the question, but treat it purely and simply as a sanitary question. And if the pseudo-moralist still has difficulty in cooperating towards the healing of this social sore he may be reminded that he himself—like everyone of us, little though we may know it—has certainly had a vast army of syphilitic and gonorrheal persons among his own ancestors during the past four centuries. We are all bound together, and it is absurd, even when it is not inhuman, to cast contempt on our own flesh and blood.

I have discussed the attitude of those who plead morality as a reason for ignoring the social necessity of combating venereal disease because, although there may not be many who seriously and intelligently adopt so antisocial an attitude, there are certainly many who are glad at need of the existence of so fine an excuse for their moral indifference or their mental indolence.* When they are confronted by this great and difficult problem they find it easy to offer the remedy of conventional morality, although they are well aware that on the large scale that remedy has long been proved to be ineffectual. They ostentatiously affect to proffer the useless thick end of the wedge at a point where it is only possible with much skill and prudence to insinuate the thin working end.

The general acceptance of the fact that syphilis and gonorrhea are diseases and not necessarily crimes or sins is the condition for any practical attempt to deal with this question from the sanitary point of view which is now taking the place of the antiquated and ineffective police point of view. The Scandinavian countries of Europe have been the pioneers in practical modern hygienic methods of dealing with venereal disease. There are several reasons why this has come about. All the problems of sex—of sexual love as well as of sexual disease—have long been prominent in these countries and an impatience with prudish hypocrisy seems here to have been more pronounced than elsewhere; we see this spirit for instance. emphatically embodied in the plays of Ibsen, and to some extent in Björnson's works. The fearless and energetic temper of the people impels them to deal practically with sexual difficulties, while their strong instincts of independence render them averse to the bureaucratic police methods which have flourished in Germany and France. The Scandinavians have thus been the natural pioneers of the methods of combating venereal diseases which are now becoming generally recognized to be the methods of the future, and they have more or less completely organized the system of putting venereal diseases under the common law and dealing with them as with other contagious diseases.

The first step in dealing with a contagious disease is to apply to it the recognized principles of notification. Every new application of the principle, it is true, meets with opposition. It is without practical result, it is an unwarranted inquisition into the affairs of the individual, it is a new tax on the busy medical practitioner, etc. Certainly notification by itself will not arrest the progress of any in-

*Much harm has been done in some countries by the foolish and mischievous practice of friendly societies and sick clubs of ignoring venereal diseases and not according free medical aid or sick pay to those members who suffer from them. This practice prevailed, for instance, in Vienna until 1907, when a more humane and enlightened policy was inaugurated. venereal diseases being placed on the same level as other diseases.

fectious disease. But it is an essential element in every attempt to deal with the prevention of disease. Unless we know precisely the exact incidence, local variations, and temporary fluctuations of a disease we are entirely in the dark and can only beat about at random. All progress in public hygiene has been accompanied by the increased notification of disease, and most authorities are agreed that such notification must be still further extended, any slight inconvenience thus caused to individuals being of trifling importance compared to the great public interests at stake. It is true that so great an authority as Neisser has expressed doubt concerning the extension of notification to gonorrhea; the diagnosis cannot be infallible, and the patients often give false names. These objections, however, seem trivial; diagnosis can very seldom be infallible (though in this field no one has done so much for exact diagnosis as Neisser himself), and names are not necessary for notification and are not indeed required in the form of compulsory notification of venereal disease which existed a few years ago in Norway.

The Scandinavian plan in a modified form has lately been established in Denmark. This little country, so closely adjoining Germany, for some time followed in this matter the example of its great neighbor and adopted the police regulation of prostitution and venereal disease. The more fundamental Scandinavian affinities of Denmark were, however, eventually asserted, and in 1906 the system of regulation was entirely abandoned and Denmark resolved to rely entirely on thorough and systematic application of the sanitary principle already accepted in the country as well as by Sweden and Norway, although something of German influence still persists in the strict regulation of the streets and the penalties imposed under some circumstances on those who harbor prostitutes in their houses. The decisive feature of the present system is, however, that the sanitary authorities are now exclusively medical. Everyone, whatever his social or financial position, is entitled to the free treatment of venereal disease. Whether he avails himself of it or not he is in any case bound to undergo treatment. Every diseased person is thus, so far as it can be achieved, in a doctor's hands. All doctors have their instructions in regard to such cases, they have not only to inform their patients that they cannot marry so long as risks of infection are estimated to be present, but that they are liable for the expenses of treatment, as well as the damages suffered, by any persons whom they may infect. Although it has not been possible to make the system at every point thoroughly operative, its general success is indicated by the entire reliance now placed on it, and the abandonment of the police regulation of prostitution. A system very similar to that of Denmark was established some years previously in Norway. The principle of the treatment of venereal disease at the public expense exists also in Sweden as well as in Finland, where treatment is compulsory.

It can scarcely be said that the principle of notification has yet been properly applied on a large scale to venereal diseases. But in some countries, notably England and the United States, where national temperament and political traditions render the system of the police regulation of prostitution impossible—even if it were more effective than it practically is—the system of dealing with venereal disease on the basis of public health has to be recognized, as not only the best but the only possible system.

In association with this, it is necessary, as is also becoming even more widely recognized, that there should be the most ample facilities for the gratuitous treatment of venereal diseases; the general establishment of free dispensaries open in the evenings is especially necessary, for many can seek advice and help only at this time. It is largely to the systematic introduction of facilities for gratuitous treatment that the enormous reduction in venereal disease in Sweden, Norway, and Bosnia is attributed. It is the absence of the facilities for treatment, the implied feeling that the victims of venereal disease are not sufferers but merely offenders not entitled to care, that has in the past operated so disastrously in artificially promoting the dissemination of preventable diseases which might be brought under control.

If we dispense with the paternal methods of police regulation, if we rely on the general principles of medical hygiene, and for the rest allow the responsibility for his own good or bad actions to rest on the individual himself, there is a further step, already fully recognized in principle, which we cannot neglect to take: We must look on every person as accountable for the venereal diseases he transmits. So long as we refuse to recognize venereal diseases as on the same level as other infectious diseases, and so long as we offer no full and fair facilities for their treatment, it is unjust to bring the individual to account for spreading them. But if we publicly recognize the danger of infectious venereal diseases, and if we leave freedom to the individual, we must inevitably declare, with Duclaux, that every man or woman must be held responsible for the diseases he or she communicates. In England and the United States the law is more unsatisfactory and helpless in this class of offense than it is in France. The mischievous and barbarous notion, already dealt with, according to which venereal disease is the result of illicit intercourse and should be tolerated as a just visitation of God, seems still to flourish in these countries with fatal persistency. In England the communication of venereal disease by illicit intercourse is not an actionable wrong if the act of intercourse has been voluntary, even although there has been wilful and intentional concealment of the disease. *Ex turpi causa non oritur actio*, it is sententiously said; for there is much dormitative virtue in a Latin maxim. No legal offense has still been committed if a husband contaminates his wife, or a wife her husband. The "freedom" enjoyed in this matter by England and the United States is well illustrated by an American case quoted by Dr. Isidore Dyer of New Orleans in his Report to the Brussels Conference on the Prevention of Venereal Diseases, in 1899: "A patient with primary syphilis refused even charitable treatment and carried a book wherein she kept the number of men she had inoculated. When I first saw her she declared the number had reached two hundred and nineteen and that she would not be treated until she had had revenge on five hundred men." In a community where the most elementary rules of justice prevailed facilities would exist to enable this woman to obtain damages from the man who had injured her or even to secure his conviction to a term of imprisonment. In obtaining some indemnity for the wrong done her, and securing the "revenge" she craved, she would at the same time have conferred a benefit on society. She is shut out from any action against the one person who injured her; but as a sort of compensation she is allowed to become a radiating focus of disease, to shorten many lives, to cause many deaths, to pile

up incalculable damages; and in so doing she is to-day perfectly within her legal rights. A community which encourages this state of things, is not only immoral but stupid.

There seems, however, to be a growing body of influential opinion, both in England and in the United States, in favor of making the transmission of venereal disease an offense punishable by heavy fines or by imprisonment.* In any enactment no stress should be put on the infection being conveyed "knowingly." Any formal limitation of this kind is unnecessary as in such a case the Court always takes into account the offender's ignorance as mere negligence, and it is mischievous because it tends to render an enactment ineffective and to put a premium on ignorance; the husbands who infect their wives with gonorrhea immediately after marriage have usually done so from ignorance; it should be at least necessary for them to prove that they have been fortified in their ignorance by medical advice. It is sometimes said that the existing law could be utilized for bringing actions of this kind and that no greater facilities should be offered for fear of increasing attempts at blackmail. The inutility of the law at present for this purpose is shown by the fact that it seldom happens that any attempt is made to utilize it, while not only are there a number of existing punishable offenses which form the subject of attempts at blackmail, but blackmail can still be demanded even in regard to disreputable actions that are not legally punishable at all. Moreover, the attempt to levy blackmail is itself an offense always sternly dealt with in the courts.

It is sometimes said that it is very well to make the individual legally responsible for the venereal disease he communicates, but that the difficulties of bringing that responsibility home would still remain. And those who admit these difficulties frequently reply that at the worst we should have in our hands a means of educating responsibility: the man who deliberately ran the risk of transmitting such infection would be made to feel that he was no longer fairly within his legal rights, but had done a bad action. We are thus led on finally to what is now becoming generally recognized as the chief and central method of combating venereal disease, if we are to accept the principle of individual responsibility as ruling in this sphere of life. Organized sanitary and medical precautions and proper legal protection for those who have been injured, are operative without the educative influence of elementary hygienic instruction placed in the possession of every young man and woman. In a sphere that is necessarily so intimate, sanitary organization and legal resort can never be all-sufficing; knowledge is needed at every step in every individual to guide and even to awaken that sense of personal moral responsibility which must here always rule. Wherever the importance of these questions is becoming acutely realized—as is notably shown at the congresses of the German Society for Combating Venereal Disease—the problem is resolving itself mainly into one of education.* And although opinion and practise in this matter are to-day more advanced in Germany than elsewhere, the conviction of this necessity is becoming scarcely less pronounced in all other civilized countries, in England and America as much as in France and the Scandinavian lands.

A knowledge of the risks of disease by sexual intercourse, both in and out of marriage—and, indeed, apart from sexual intercourse altogether—is a further stage of that sexual education which must begin so far as the elements are concerned at a very early age. Information about venereal disease should not be given until adolescence. It is unnecessary and undesirable to impart medical knowledge to young boys and girls, and to warn them against risks they are yet little liable to be exposed to. It is when the age of strong sexual instinct, actual or potential, begins, that the risks under some circumstances of yielding to it need to be clearly present to the mind. No one who reflects on the actual facts of life ought to doubt that it is in the highest degree desirable that every adolescent youth and girl ought to receive some elementary instruction in the general facts of venereal disease, tuberculosis, and alcoholism. These three "plagues of civilization" are so widespread, so subtle, and so manifold in their operation, that everyone comes in contact with them during life, and that everyone is liable to suffer, even before he is aware, perhaps hopelessly and for ever, from the results of that contact. Vague declamation about immorality and vaguer warnings against it have no effect and possess no meaning, while rhetorical exaggeration is unnecessary. A very simple and concise statement of the actual facts concerning the evils that beset life is quite sufficient and adequate and quite essential. To ignore this need is only possible to those who take a dangerously frivolous view of life.

It is the young woman as much as the youth who needs this enlightenment. There are still some persons so ill-informed as to believe that though it may be necessary to instruct the youth, it is best to leave his sister unsullied, as they consider it, by a knowledge of the facts of life. This is the very reverse of the truth. It is desirable indeed that all should be acquainted with facts so vital to humanity, even although not themselves personally concerned. But the girl is even more concerned than the youth. A man has the matter more within his own grasp, and, if he so chooses, he may avoid all the grosser risks of contact with venereal disease. But it is not so with the woman. Whatever her own purity, she cannot be sure that she may not have to guard against the possibility of disease in her future husband, as well as in those to whom she may entrust her child. It is a possibility which the educated woman, so far from being dispensed from, is more liable to encounter than is the working-class woman, for venereal disease is less prevalent among the poor than the rich. The careful physician, even when his patient is a minister of religion, considers it his duty to inquire if he has had syphilis, and the clergyman of most severely correct life recognizes the need of such inquiry, and may, perhaps, smile, but seldom feels himself insulted. The relationship between husband and

*Modern democratic sentiment is opposed to the sequestration of a prostitute merely because she is diseased. But there can be no reasonable doubt whatever that if a diseased prostitute infects another person, and is unable to pay the very heavy damages which should be demanded in such a case she ought to be secluded and subjected to treatment. That is necessary in the interests of the community. But it is also necessary, to avoid placing a premium on the commission of an offense which would insure gratuitous treatment and provision for a prostitute without means, that she should be furnished with facilities for treatment in any case.

*The large volume, entitled *Sexualpädagogik* (1907), containing the proceedings of the third of these congresses, almost ignores the special subject of venereal disease, and is devoted to the questions involved by the general sexual education of the young which, as many of the speakers maintained, must begin with the child at his mother's knee.

wife is even much more intimate and important than that between doctor and patient, and a woman is not dispensed from the necessity of such inquiry concerning her future husband by the conviction that the reply must surely be satisfactory. Moreover, it may well be in some cases, that if she is adequately enlightened she may be the means of saving him, before it is too late, from the guilt of premature marriage and its fateful consequences, so deserving to earn his everlasting gratitude. Even if she fails in winning that she still has her duty to herself and to the future race which her children will help to form.

We must fully face the fact that it is the woman herself who must be accounted responsible, as much as a man, for securing the right conditions of a marriage she proposes to enter into. In practice, at the outset, that responsibility may no doubt be in part delegated to parents or guardians. It is unreasonable that any false delicacy should be felt about this matter on either side. Questions of property and of income are discussed before marriage, and as public opinion grows sounder none will question the necessity of discussing the still more serious question of health, alike that of the prospective bridegroom and of the bride. An incalculable amount of disease and marital unhappiness would be prevented if before an engagement was finally concluded each party placed himself or herself in the hands of a physician and authorized him to report to the other party. Such a report would extend far beyond venereal disease. If its necessity became generally recognized, it would put an end to much fraud which now takes place when entering the marriage bond. It constantly happens at present that one party or the other conceals the existence of some serious disease or disability which is speedily discovered after marriage, sometimes with a painful and alarming shock—as when a man discovers his wife in an epileptic fit on the wedding night—and always with the bitter and abiding sense of having been duped. There can be no reasonable doubt that such concealment is an adequate cause of divorce. Sir Thomas More doubtless sought to guard against such frauds when he ordained in his *Utopia* that each party should before marriage be shown naked to the other. The quaint ceremony he describes was based on a reasonable idea, for it is ludicrous, if it were not often tragic in its results, that any person should be asked to undertake to embrace for life a person whom he or she has not so much as seen.

It may be necessary to point out that every movement in this direction must be the spontaneous action of individuals directing their own lives according to the rules of an enlightened conscience, and cannot be initiated by the dictation of the community as a whole enforcing its commands by law. In these matters law can only come in at the end, not at the beginning. In the essential matters of marriage and procreation laws are primarily made in the brains and consciences of individuals for their own guidance. Unless such laws are already embodied in the actual practice of the great majority of the community, it is useless for parliaments to enact them by statute. They will be ineffective, or else they will be worse than ineffective by producing undesigned mischiefs.

It is for this reason that, notwithstanding various attempts at legislation in this direction, it is still premature to introduce the principle of compulsory certificates of health at marriage. So long ago as 1858 Diday of Lyons proposed that all persons without exception should be obliged to possess a certificate of health and disease, a kind of sanitary passport. This would be an excellent provision, but it is still too far ahead to be worth practical advocacy. Duclaux considered that the candidate for marriage should possess a certificate of health in much the same way as the candidate for life assurance, the question of professional secrecy no more coming into one question than into the other. There is no reason why such certificate, of an entirely voluntary character, should not become customary among those persons who are sufficiently enlightened to realize all the grave personal, family, and social issues involved in marriage. The system of eugenic certification, as originated and developed by Galton, will constitute a valuable instrument for raising the moral consciousness in this matter. Galton's eugenic certificates would deal mainly with the natural virtues of superior hereditary breed—"the public recognition of a natural nobility"—but they would include the question of personal health and personal aptitude.*

The question arises as to the best person to impart this instruction. There can be little doubt that before puberty the parents, and especially the mother, are the proper instructors of their children in esoteric knowledge. But after puberty the case is altered. The boy and girl are becoming less amenable to parental influence, there is greater shyness on both sides, and the parents rarely possess the more technical knowledge that is now required. At this stage it seems that the assistance of the physician should be called in. The plan usually adopted, and now widely carried out, is that of lectures setting forth the main facts concerning venereal diseases, their dangers, and allied topics. This method is excellent. Such lectures should be delivered at intervals by medical lecturers at all urban, educational, manufacturing, military, and naval centers, wherever indeed a large number of young persons are gathered together. It should be the business of the central educational authority either to carry them out or to enforce on those controlling or employing young persons the duty of providing such lectures. The lectures should be free to all who have attained the age of sixteen.

In Germany the principle of instruction by lectures concerning venereal diseases seems to have become established, at all events so far as young men are concerned, and such lectures are constantly becoming more usual. In England and the United States very little has yet been done in this direction, but in the United States, at all events, opinion in favor of action is rapidly growing.*

Something is clearly needed beyond these lectures on these matters. It should be the business of the parents or other guardians of every adolescent youth and girl to arrange that once at least at this period of life there should be a private, personal interview with a medical man in which the venereal risks and possibilities of life would be clearly pointed out. In the case of girls, a woman doctor would usually be

*F. Galton, *Inquiries Into Human Faculty,* Every Man's Library ed., pp. 211, *et seq.*

*An important auxiliary method of carrying out the task of sexual hygiene, and at the same time of spreading useful enlightenment is furnished by the method of giving to every syphilitic patient in clinics where such cases are treated a card of instruction for his guidance in hygienic matters, together with a warning of the risks of marriage within four or five years after infection, and in no case without medical advice. Such printed instruction, in clear, simple, and incisive language, should be put into the hands of every syphilitic patient as a matter of routine, and it might be as well to have a corresponding card for gonorrheal patients. This plan has already been introduced at some hospitals, and it is incomprehensible that so simple and unobjectionable a precaution is not universally adopted.

preferred. Sex is properly a mystery, and to the unspoilt youth it is instinctively so; except in an abstract and technical way it cannot properly form the subject of lectures. In a private and individualized conversation between the novice in life and the expert, it is possible to say many necessary things that could not be said in public, and it is possible, moreover, for the youth to ask questions which shyness and reserve make it impossible to put to parents, while the convenient opportunity of putting them naturally to the expert otherwise seldom or never occurs. Must youths have their own special ignorances, their own special difficulties, difficulties and ignorances that could sometimes be resolved by a word? Yet it by no means infrequently happens that they carry them far on in to adult life because they have lacked the opportunity, or the skill and assurance to create the opportunity, of obtaining enlightenment.

It must be clearly understood that these talks are of medical, hygienic, and physiological character; they are not to be used for retailing moral platitudes. To make them that would be a fatal mistake. The young are often very hostile to merely conventional moral maxims, and suspect their hollowness, not always without reason. The end to be aimed at here is enlightenment. Certainly knowledge can never be immoral, but nothing is gained by jumbling up knowledge and morality together.

In emphasizing the nature of the physician's task in this matter as purely and simply that of wise practical enlightenment, nothing is implied against the advantages, and indeed the immense value in sexual hygiene, of the moral, religious, ideal elements of life. It is not the primary business of the physician to inspire these, but they have a very intimate relation with the sexual life, and every boy and girl at puberty, and never before puberty, should be granted the privilege—and not the duty or the task—of initiation into those elements of the world's life which are at the same time natural functions of the adolescent soul. Here, however, is the sphere of the religious or ethical teacher. At puberty he has his great opportunity, the greatest he can ever obtain. The flower of sex that blossoms in the body at puberty has its spiritual counterpart which at the same moment blossoms in the soul. The Churches from of old have recognized the religious significance of this moment, for it is this period of life that they have appointed as the time of confirmation and similar rites. With the progress of the ages, it is true such rites become merely formal and apparently meaningless fossils. But they have a meaning nevertheless and are capable of being again vitalized. Nor in their spirit and essence should they be confined to those who accept supernaturally revealed religions. They concern all ethical teachers, who must realize that it is at puberty that they are called upon to inspire or to fortify the great ideal aspirations which at this period tend spontaneously to arise in the youth's or maiden's soul.

It is not for the physician to complicate and confuse his own task as teacher by mixing it up with considerations which belong to the spiritual sphere. But in carrying out impartially his own special work of enlightenment he will always do well to remember that there is in the adolescent mind a spontaneous force working on the side of sexual hygiene. Those who believe that the adolescent mind is merely bent on sensual indulgence are not less false and mischievous in their influence than are those who think it possible and desirable for adolescents to be preserved in sheer sexual ignorance. However, concealed, suppressed, or deformed—usually by the misplaced and premature zeal of foolish parents and teachers—there arise at puberty ideal impulses which, even though they may be rooted in sex, yet in their scope transcend sex. These are capable of becoming far more potent guides of the physical sex impulse than are merely material or even hygienic considerations.

It is time to summarize and conclude this discussion of the prevention of venereal disease which, though it may seem to the superficial observer to be a medical and sanitary question outside the psychologist's sphere, is yet seen on closer view to be intimately related even to the most spiritual conception of the sexual relationships. Not only are venereal diseases the foes to the finer development of the race, but we cannot attain to any wholesome and beautiful vision of the relationships of sex so long as such relationships are liable at every moment to be corrupted and undermined at their source. We cannot yet precisely measure the interval which must elapse before, so far as Europe at least is concerned, syphilis and gonorrhea are sent to that limbo of monstrous old dead diseases to which plague and leprosy have gone and smallpox is already drawing near. But society is beginning to realize that into this field also must be brought the weapons of light and air, the sword and the breastplate with which all diseases can alone be attacked. As we have seen, there are four methods by which in the more enlightened countries venereal disease is now beginning to be combated.* (1) By proclaiming openly that the venereal diseases are diseases like any other disease, although more subtle and terrible than most, which may attack anyone, from the unborn baby to its grandmother, and that they are not, more than other diseases, the shameful penalties of sin, from which relief is only to be sought, if at all, by stealth, but human calamities. (2) By adopting methods of securing official information concerning the extent, distribution, and variation of venereal disease, through the already recognized plan of notification and otherwise, and by providing facilities for treatment, especially for free treatment, as may be found necessary. (3) By training the individual sense of moral responsibility so that every member of the community may realize that to inflict a serious disease on another person, even only as a result of reckless negligence, is a more serious offense than if he or she had used the knife, or the gun, or poison, as the method of attack, and that it is necessary to introduce special legal provision in every country to assist the recovery of damages for such injuries, and to inflict penalties by loss of liberty or otherwise. (4) By the spread of hygienic knowledge so that all adolescents, youths and girls alike, may be furnished at the outset of adult life with an equipment of information which will assist them to avoid the grosser risks of contamination, and enable them to recognize and avoid danger at the earliest stages.

A few years ago, when no method of combating venereal disease was known except that system of police regulation which is now in its decadence, it would have been impossible to bring forward such considerations as these; they would have seemed Utopian. To-day they are not only recognizable as practical, but they are being actually put into

*I leave out of account, as beyond the scope of the present paper, the auxiliary aids to the suppression of venereal diseases furnished by the promising new methods, only now beginning to be understood, of treating or even aborting such diseases. See *e.g.* Metchnikoff, "The New Hygiene," 1906.

practice, although, it is true, with very varying energy and insight, in different countries. Yet it is certain that in the competition of nationalities, as Max von Niessen has well said, "that country will best take a leading place in the march of civilization which has the foresight and courage to introduce and carry through those practical movements of sexual hygiene which have so wide and significant a bearing on its own future, and that of the human race generally."

SIGNIFICANCE OF WASH WATER EXAMINATIONS FOR GASTRIC CELLS IN THE DIAGNOSIS OF ATROPHIC GASTRITIS; REPORT OF TWO CASES.

By ANTHONY BASSLER, M.D.,

NEW YORK.

In the field of gastroenterology few diseases present more difficulties in the way of accurate diagnosis than do the various types of chronic gastritis. For of common and widespread disorders most of the diagnoses are still made by inference from a long line of most varied subjective symptoms, the presence of a low hydrochloric acidity, a lowering of the quantities of the gastric enzymes, and an increase in the amounts of incorporated mucus and leucocytes found present in a test meal.

In forming deductions from the subjective symptoms alone we can easily fall into error, because other gastric conditions may give a like history of complaints and because there are no specific subjective symptoms of this chronic disease. Life in our large cities is so artificial and irregular, particularly in the dietetic way, that a succession of slight neurotic gastric disturbances could ensue in many persons the symptoms of which together might establish the anamnesis of a chronic gastritis.

The standard of hydrochloric acidity differs in different stomachs, and what would be a normal acidity in one might be a high or low acidity in another. Also, the running acidity in the same stomach is often changing in degree. This may be seen in normal conditions under a change in the character and quantities of food. The difference in the total normal acidities between the Reigel and Ewald meals (adaptation juice of Pawlow) proves this to be true for the one meal, and this raising or lowering acidity under favorable conditions for its progress may establish for a short time a different standard of acidity in the same stomach. Thus it is that any change in the eating habits is important to consider when figuring an abnormal acidity. In the gastric neuroses the widest range of HCl content is possible. There are the two extremes of the hyperchlorhydria on the one hand and the unquestioned instances of short neurotic achlorhydria on the other, not to speak of heterochylia and the effects of a depressed mental condition in the individual on the character of the gastric juice secreted during or after a meal taken at the time. Unless, in any gastric condition with symptoms, the hydrochloric acid content continues steadily too high or too low, or is making an increasing progress to an abnormal standard, it cannot be regarded as of much significance. This requires the giving of more than one test meal before the degree of acidity can be determined as due to a gastritis.

With the quantity of the enzymes, mucus from the stomach, and a number of leucocytes, it is different. Here we deal with definite suggestive signs. When the enzymes are low in quantity the gastric juice necessarily lacks in digesting power, and this usually means organic changes in the structure of the cells in the gastric tubules, their detachment from the tubules, some circulatory disturbances in the walls of the stomach, or any combination of the above. That a juice may be low in its acidity and still possess a normal amount of the proenzymes can be seen in some of the neurotic hypochlorhydrias. Usually it is practical to infer that the degree of acidity is a fair standard upon which to judge the amount of the enzymes present, but such a rule cannot be depended upon in the chronic gastritides. In these conditions the more delicate peptic cells are usually the first to be affected and they may be seriously degenerated, and, therefore, their secreting function modified, while still the acid cells are functionating comparatively well. The general employment of the Mett tubes for proteolysis and the graduated milk tests for chymosis will prove this to be so.

In the early course of a chronic gastritis the stomach secretes an increased amount of mucus. Only rarely does a chronic gastritis begin without this increase. But this increased secretion may become arrested in the early course of the disease and not again return. Then there is the one condition of catarrhal inflammation with much mucus accompanied with a high acidity and sufficient enzymes (gastritis acida) on the one hand, and a gastritis with practically no mucus, no hydrochloric acid, and no enzymes (advanced atrophic gastritis) on the other. The first condition plainly deals with a digesting stomach; the other with an organ which is practically only a receptacle for food and in which the only digestion is the continued amylolytic one of the ptyalin. As the first, as well as other types of gastritis may progress to the last, how are we to be able to determine the crossing point between the two if we depend too much upon the estimation of the amount of incorporated mucus alone in our diagnoses of the atrophic conditions?

The number of free leucocytes that a stomach contains is a very important diagnostic sign of organic disease, and to their number as well as to their character we should give more attention than is now commonly done. Unfortunately, we have no practical good way of counting them here as is done with the blood. With the latter the means are comparatively accurate. We draw the blood into a perfectly graduated tube and dealing with a small known quantity of diluant and the counting scale we can be practically positive of their numbers. But with the stomach we deal with a large hollow viscus by means of a quantity of fluid contents (some of which escapes into the duodenum and some cannot be withdrawn from the stomach) and this fluid must stand for hours before we are enabled to find the leucocytes. Furthermore, even with the centrifuge they do not all settle to the bottom. At best, we can only infer their increase and to do this fairly accurately means long practice in the examination of wash waters. The free nuclei may be mentioned in this connection as of little value in the diagnostic way, except that they do not seem to be as numerous when the acid and enzymes are low. They are the digested remains of the bodies of any of the cells that have lined the structures from the lips to the pylorus, and also from the mucous corpuscles and leucocytes.

It is in the weighing of the above-mentioned findings that most of the diagnoses of chronic gas-

tritis are made. In the mild and medium cases when the gastric cell exfoliation is not present to any practical extent the above data must serve for the basis of our deductions. But from the standpoint of diagnosis, prognosis, and therapy in the advancing destructive cases of gastritis more than these are required. In the atrophic conditions, this is made possible by a careful examination of the numbers, the type, and state of health of the gastric cells found free in the stomach. The textbooks on the diseases of the stomach do not give significance to the value of such examinations. Here it is evident that we deal with the organic cell of the *tunica propria* itself, and the technique, as well as the method of examination, is simple. Since they cannot readily be made out in the thick mass of a test meal the stomach must be empty when we go after them, and this means the lavage of the jejune morning, after a light supper taken early the evening before, and a night of freedom from digestion. By these means the cells when exfoliating from the free surface of the stomach or desquamating from the tubules will collect in sufficient numbers for their discernment.

The technique that I have generally employed, and which was followed in the two cases herein reported, is the same as that described by me before. ("Gastric Exfoliation as a Feature in the Production of Acute Gastric Ulcer," Medical Record, November 30, 1907.) It is desirable to begin by aspirating the empty stomach before the ingestion of the compound saline solution. For this purpose I employ my regular test meal bottle. ("Test-meal Extraction," *N. Y. State Medical Journal*, June, 1908.) The disturbing factor in the examination of such aspirated fluid as may be obtained before the giving of the saline water is that generally this fluid contains too much mucus for a careful scrutiny of the cells. Still they can often be made out and then they are found not so much changed as they are liable to be when drawn hours later from the standing wash water, even when the compound saline solution had been employed. When any organic cells outside of the living body are subjected to the continued action of water they usually undergo a hydrolytic process, swell, change in contour, and do not stain as definitely as when in the tissues or when freshly drawn. The gastric cells are no exception to this rule. To prevent this, in so far as it is possible, it is desirable to employ for the washing purpose a solution which in character and specific gravity approximates that of the blood. This is done by the addition of salines. The installation that was used contained 250 c.c. of water to which were added 21 grains of sodium chloride, one grain each of sodium sulphate, sodium carbonate, and sodium phosphate, and 1½ grains of potassium chloride. This is drank, or run down through the tube, the patient is made to exercise vigorously, or the fluid is agitated in the stomach by sharp taps with the hand upon the abdomen over the gastric region; it is aspirated after five minutes and permitted to stand for several hours, the upper part of the fluid is syphoned off, and the sediment, in small lots, centrifuged for examination by the microscope. The stains which have served me best are one-half per cent. aqueous eosin, one per cent. methyl eosin and hemotoxylin, Biondi's polychrome methylene and carbol fuchsin. I would recommend for general use the eosin and hemotoxylin.

The acid cells from the stomach stain readily with most of the anilin dyes. They are seen between the leucocyte and squamous epithelium in size and their main features are their confluent stippling of the cell protoplasm with eosinophilic granules and their well-defined nucleus. In shape they may be described as irregular although most of them are oval. With the eosin and hemotoxylin stain, which serves well in differentiating the acid from the peptic cells (the first taking the eosin, the latter the hemotoxylin), the nuclear membrane is usually well defined. The nucleus itself is usually lighter and a trifle larger than those in the peptic cells and stains in a blotchy way. These cells when desquamating in any numbers are easy to find, and upon their presence the main dependence must be placed in the diagnosis of atrophic gastritis.

The peptic cells offer much greater difficulties in the way of their finding and discrimination than do any of the other organic elements found in the stomach. They stain poorly, the body just barely, the nucleus much better. With care and patience in the search they can often be seen, but never as plainly as the acid ones. Their cell protoplasm is indistinct and with the hemotoxylin stain is found faintly bluish in color. At best they take eosin, or, in fact, any of the anilin stains, very poorly. Their nucleus stains deeply and generally uniformly throughout. Neither the nuclear membrane nor nuclear granules can be distinctly discerned. This also differentiates them from the acid cells. The nucleus itself is seldom found oval as is often the case in the parietal cells. They are much smaller in size than the latter, being in size between them and the leucocyte, for the mononuclear variety of which they may be mistaken. Because their protoplasm digests away so readily (when the cells are free) and because of their poor staining properties and the question of their presence even if seen, the search for them need not be continued when numbers of the more plainly recognized acid cells are discovered. Sometimes they take the carbol fuchsin stain better than they do the hemotoxylin. Some of the free nuclei noted are undoubtedly from these cells, because I have seen such nuclei with just a shred or the faintest band of the characteristically stained protoplasm about them.

The columnar cells from the stomach are not difficult to make out. It must be remembered that in the posterior nares and the upper half of the pharynx the epithelium is of the cylindrical variety and these may be shed and swallowed. The cilia of these cells would serve to distinguish them from the gastric epithelium. They stain better than the peptic cells, although not so well as the acid. Their shape is characteristic, their protoplasm is not granular, and they have a long, flat looking nucleus which is almost in the center between the ends of the cell, while in the acid and peptic cells the nucleus is generally nearer to the edge of the protoplasm. They are easily detached by the stomach tube and thus are not so significant in this connection, unless exfoliating in large numbers, as the peptic juice secreting cells would be. They are often found in groups, and hemotoxylin stains them well.

In cases of atrophic gastritis, particularly, there may be seen a ring of cells (cast) more or less complete, which, in my opinion, consists of groups from the depths of the tubules. Sometimes a mass of rounded or cuboidal shaped cells may be exfoliated from the lower regions of the infundibula and these would strongly resemble the above. The goblet cells are rarely found and are not difficult to differentiate from the true columnar.

Case I.—January 3, 1906. T. B., age fifty-three years. Born in Ireland. Occupation, ex-police-

man. Family history, negative. Personal history, had measles and diphtheria when a child. Fifteen years ago had a tapeworm which was removed. A second one was removed three years ago. Up to seven years ago he drank intemperately of al-

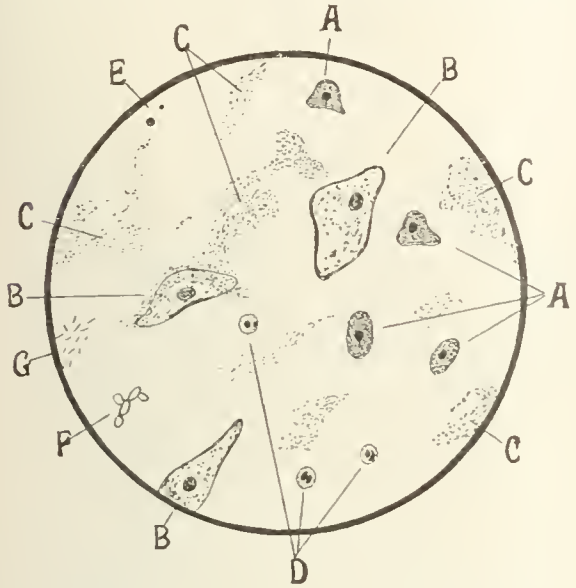

FIG. 1.—View through the Microscope of the Sediment from Case I, of Atrophic Gastritis. A, acid or parietal cells; B, squamous epithelium; C, mucus from the stomach; D, leucocytes; E, free nuclei; F, yeast fungi; G, bacilli. X 460.

coholic liquors, mostly whiskey; since then he has abstained completely. Other than his gastric trouble he has had no other illness.

Gastric history: Had stomach trouble for fifteen years. During this time has had intervals of relief, longer in the beginning, but in the past year and seven months the distress has been continuous. First symptoms were weight and distress in the epigastrium after eating. In the past eighteen months lost 47 pounds in weight. "Began to get nervous just about the time the loss of weight started; now I'm irritable, don't know what I want or what to do, and cannot sleep nights." Has a craving appetite (bulimia) and whenever he takes food has a wild roaring and tumbling sensation in the stomach. Constantly belching gas which is odorless and tasteless. Feels very weak physically and cannot walk more than a few blocks without resting. Bowels obstinately constipated.

Physical examination: Talks excitedly and has an anxious look in his face. Seems to lack the power of consecutive thought. Weight, 141 pounds. Body shows that he has lost considerably in weight. Skin dry and sallow looking. Examination of heart, lungs, and liver revealed nothing abnormal. Urine contained one-half per cent. of albumin and a considerable number of casts. Has a well marked gastric splash (three hours after breakfast). Greater curvature of the stomach lies above the umbilicus. The patient winces on pressure over the stomach and becomes nauseated when pressure is made in the epigastrium. Tongue coated. Was highly nervous and apprehensive during the examination.

Analysis of Ewald test meal extracted the next morning. Looks well digested. Return 110 c.c. Incorporated mucus not increased in quantity. Congo and litmus negative. Free HCl absent. Combined HCl 3°. Total acidity, 9°. Starches well digested. Fehling's test for sugar positive and quick. Very little lactic acid. A loop of the test meal taken from the filter paper and examined unstained, showed a number of leucocytes and squamous cells, the starches in a good state of digestion, and no Boas-Oppler bacilli. Subsequent estimation of the quantities of enzymes with the Mett tubes (for pepsin) and milk for chymosin showed a very low digesting power in the gastric juice.

The next morning before breakfast I aspirated his fasting stomach and drew out 17 c.c. of thick fluid, which on examination consisted mostly of mucus (most of this was probably swallowed during the night). He then drank 250 c.c. of the combined saline water which was withdrawn, permitted to stand for four hours, syphoned down to 70 c.c., centrifuged in lots and examined microscopically with the following findings: Acid cells from the gastric tubules present in large numbers; some peptic cells; leucocytes numerous; free nuclei and mucus present in all fields; squamous cells abundant; some yeast fungi and bacilli found.

Diagnosis: Advanced atrophic gastritis and chronic nephritis.

The subsequent history of this patient is worth relating. Under dilute hydrochloric acid, taken one, two, and three hours after his meals and acid gastric douches, a diet free from meats, eggs, and milk, his stomach at the end of two weeks showed a total hydrochloric acid acidity, after an Ewald meal, of 9° (all combined), and a total acidity of 13°. But he complained that he felt no better and had lost another pound and a half in weight. Although the results from his treatment seemed encouraging he evidently felt otherwise about it, so he continued his rounds of private physicians and dispensaries until he landed a bed patient in one of the large general hospitals in the city. Here, a diagnosis of probable carcinoma of the stomach was made, an exploratory incision was performed (nothing malignant or surgical was found), and the patient died three days afterward of an acute exacerbation of his chronic nephritis, induced probably by the ether given at the time of his operation.

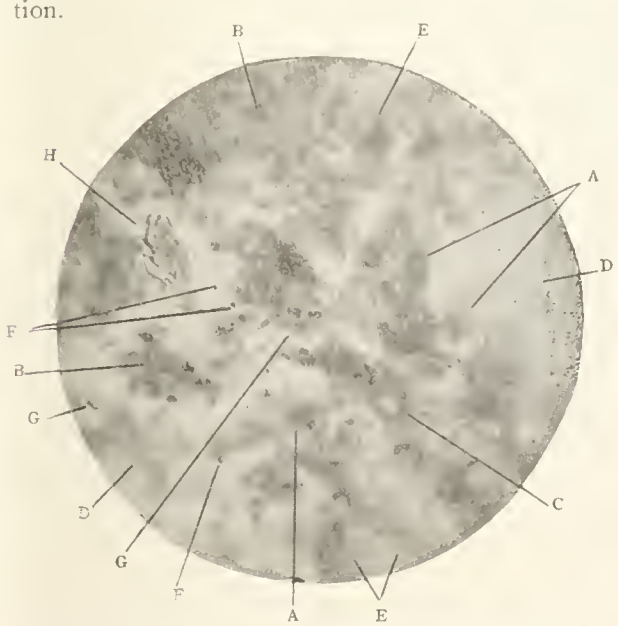

FIG. 2.—Photomicrograph of the Centrifuged Wash Water from Case II of Atrophic Gastritis. Stained with eosin and hematoxylin. A, acid cells from the gastric tubules; B, peptic cells from the gastric tubules, also the cuboidal cells from the lower parts of the infundibula of the glands (mostly the first); C, rings of cells from the tubules (casts of the glands); D, columnar epithelium from the stomach; E, squamous cells; F, free nuclei; G, leucocyte; H, vegetable substance. X 560.

CASE II.—April 4, 1907. Miss M. S., twenty-five years old. American birth and of good family. Occupation, at home. Family history, a maternal uncle died of carcinoma ventriculi at the age of fifty-one years, otherwise negative. Personal

history, was a seven-month child; had variola, scarlatina, and parotiditis when a child; began menstruating when seventeen years of age; had typhoid fever at twenty. "Never was strong physically." Habits good.

Gastric history: Had stomach trouble for seven years. It began shortly after her attack of typhoid fever and its onset was gradual. At times, when careful with what she ate, was comparatively free from distress. Various acute attacks in the past had been diagnosed as "gastritis," "nervous indigestion," and "weak stomach." Always felt best when away from city life. Complains of a sensation of weight and fullness in the epigastrium after meals. When the stomach is troubling her has much palpitation of the heart. Has often vomited a watery looking fluid (probably mucus). Has many headaches, and pains and a tired feeling in the calves of her legs. Has a bitter taste in her mouth mornings. Two years ago, when her stomach was not troubling her especially, she ate rather heavily one evening of chicken salad, after which she was taken acutely ill, had to go to bed, where she remained for ten days with a gastric disturbance accompanied with an elevation of temperature and which at the time was diagnosed as "gastric fever." Bowels constipated, but move with small doses of fluid extract of cascara. Has lost no weight.

Physical examination: Weight, 127 pounds. Looks moderately anemic. Heart and lungs normal. Has a systolic hemic murmur over the body of the heart and a bruit in the external jugular veins. Blood examination showed 3,400,000 reds, 7,000 leucocytes and 73 per cent. of hemoglobin. Abdomen well formed but walls have poor contracting power. Lower border of the stomach 2 c.m. below the umbilicus. Hepatic flexure of the colon and right kidney also displaced downward. Stomach very tympanitic. No splash on vibrating over the stomach, but slight succussion sounds on shaking the body from side to side. Stomach apparently empty of food (four hours after a breakfast consisting of orange juice, a roll, and hot milk). An indefinite sense of distress on pressure in the gastric region, but no actual pain. Examination of urine showed a phosphaturia, otherwise normal.

Ewald test meal extracted two days later. Return 55 c.c. and looks like fine oatmeal water. Free HCl absent. Combined HCl, 10°. Total acidity, 14°. Starches well digested. Mett tubes showed poor proteolysis and chymosin reaction 1:20. Many yeast fungi and sarcinæ.

Examination of the sediment in the saline water, which was permitted to stand for five hours, showed many acid and peptic cells, a few columnar, one goblet cell and an abundance of squamous cells, small rolls of discolored mucus, an increased amount of leucocytes and free nuclei. Some of the gastric cells were perfect casts of the tubules.

Diagnosis: Advanced atrophic gastritis, and anemia.

Subsequent history: Under a carefully selected bland diet, tonics, general hygienic measures, and intragastric douching with a weak solution of silver nitrate, 1:1,000, she improved perceptibly. Dilute hydrochloric acid taken after her meals had to be discontinued because of the distress it caused. The taking of fully peptonized milk with her meals helped in the general digestion of other foods taken at the same time. After four months of treatment the acid cells were no longer to be found free in the stomach (on three occasions). She gained nine pounds in weight. Her highest acidity, after an Ewald meal, was found two months after the treatment had been instituted, and was total HCl, 17° and total acidity, 19°. On January 9, 1908, she again came under observation, having gotten acutely worse a short time before. The total HCl was then found to have dropped to 9° and the gastric cells were again found in the morning stomach as before.

NERVE ANASTOMOSIS IN INFANTILE PARALYSIS.

By KARL OSTERHAUS, M.D.,

NORFOLK, VIRGINIA.

In the entire field of Orthopedic Surgery there is nothing which deserves more care and study on the part of the surgeon than the treatment of infantile paralysis, and the disabling and unsightly deformities incident to this disease. Undoubtedly a great many of these deformities could be prevented or ameliorated by the prompt institution of treatment during the acute stages of the disease tending to limit the area involved, or when the acute symptoms have subsided, by fixation of the limb in its normal position by a suitable splint or other form of apparatus, to prevent the contractures which always follow lack of treatment. It is strange indeed that a correct diagnosis is not more often made in this affection, which is so commonly met with both in epidemics and sporadically, and even when made, little is attempted to prevent deformity. Too often are these deformities allowed to go unchecked by the general practitioner, except perhaps for some vague directions to the parents to get a brace from an instrument maker and give the child massage and electricity.

When seen by the orthopedist these deformities usually require some form of operation for their correction and braces to preserve the results. But do the operations of tendon transference, etc., commonly used to-day meet all the requirements of this condition? Doubtless they go a long way toward improving the growth and function of the affected limb, when combined with the use of appropriate mechanical support, but would it not be infinitely more satisfactory if by repairing or replacing the affected nerves, we could restore the function of the paralyzed muscles and obtain a useful limb, instead of having to depend for years on some supporting apparatus? That the transplantation of nerves is feasible can no longer be doubted, and this fact has been proved not only by experiments on animals, but by the great improvement which has followed in those cases of infantile paralysis in which it has been employed.

The various operative measures commonly used at the present time may be classified as follows: Tenotomy and myotomy, tendon and muscle transplantation, astragalectomy, arthrodesis, osteotomy.

Excellent results may be obtained from the first mentioned in the milder grades of deformity, as severing the overactive muscles or tendons tends to restore the normal relation in the limbs, but some form of apparatus is necessary for some time afterwards to prevent recurrence.

Nicoladoni's method of tendon transference, which consists in attaching the distal end of the tendon of a paralyzed muscle to a healthy muscle in order to restore the function of the former, is far from giving the results expected of it, and when this is done dependence must be placed largely on artificial support.

Far more satisfactory is Lange's method, as im-

proved on by Hoffa, R. T. Taylor, Dane, and others, by which the healthy tendon is either sutured directly to the periosteum, passed through a bony canal, and then fastened to the periosteum, or after being passed through the bony canal is then doubled back on itself and there sutured. Lengthening contracted tendons by means of white silk sutures and then attaching them to the periosteum has much to commend it, and a recent report in the *Boston Medical and Surgical Journal* by Bradford and Soutter of a series of thirty-five cases in which this latter method was used, shows the excellent results obtained by it at their hands.

The muscle transplantations usually employed by Hoffa and others consist in shifting one head of the pronator radii teres to the external condyle of the humerus, thus making it act as a supinator; conversion of the sartorius into an extensor of the leg by implanting it into the quadriceps extensor; and the transference of a part of the trapezius in the deltoid. Recently Sachs has reported an operation in which he transplanted the whole origin of the pectoralis major over the paralyzed deltoid with almost perfect results.

Arthrodesis and astragalectomy may be employed after other methods have failed, or in cases in which the paralysis is so extensive as to render the other operations useless. A firmer joint is perhaps obtained by the former than the latter, though neither should be attempted in young children, as the bones must be fully ossified to insure absolute absence of motion. Osteotomy is to be employed only after other attempts at correction of the malposition have failed.

The writer cannot lay too much emphasis on the necessity of some form of mechanical support after each of these operative procedures, combined with massage, baking, electricity, active and passive motion, to prevent recurrence of the deformity and to aid the sound muscles in adapting themselves to their new functions.

Each of these procedures is, however, more or less of a makeshift and aims rather toward correction of the deformity than the cure of the disease. In going over the available literature on neuroplasty or nerve anastomosis, the writer was astonished at the scarcity of reported cases in which it had been applied to infantile paralysis, though there are a number of cases on record in which it has been used to advantage in regenerating traumatically paralyzed nerves.

A great many experiments have been worked out by various investigators, notably Howell of the University of Michigan, but these nearly all have to do with the regeneration of traumatically divided nerves. Spitzy's experiments and observations are the most noteworthy which deal specifically with infantile paralysis, and his conclusions agree in the main with those of Howell, Oppenheim, Kennedy, and others, namely, that a small living central nerve may regenerate a large degenerated peripheral stump.

The results of the investigations of these men certainly seem to point to ultimate success in the application of neuroplasty to the treatment of infantile paralysis, but as R. T. Taylor aptly points out, "we must bear in mind that often the adjacent nerve from which we hope to obtain central connection, is also impaired in function by the disease." In the opinion of the writer, based on the studies and reports of various surgeons, and on his own limited experience in this work, the conditions following anterior poliomyelitis and injuries to a nerve are to a great extent analogous, and whether we accept the peripheral or the central theory of nerve regeneration, the anastomosis between a central healthy living nerve and a degenerated peripheral stump, in certain selected cases, gives promise of far better success than any of the other operative measures in use at the present day. In any case the operation, if conservatively done, can do no harm, and we can always fall back on tendon transplantation in event of failure.

According to Spiller the chief dangers in operating on nerves in infantile paralysis are delayed union and overgrowth of connective tissue at the site of the wound. In the case of a large nerve such as the peroneal he advocates splitting the healthy nerve transversely and longitudinally and suturing the split-off bundle of fibers to the diseased nerve. When, however, only a small nerve, such as that supplying the tibialis anticus is involved, he thinks that by simply splitting the healthy nerve and inserting the peripheral end of the diseased nerve into the slit enough fibers are cut to insure union and regeneration. Spitzy, on the other hand, advocates this latter method (indirect anastomosis) only, thus minimizing the danger of injury to the unaffected nerve fibers.

The various methods of anastomosing nerves have been classified by Charles H. Frazier as follows:

1. End-to-end anastomosis of the peripheral segment of the affected nerve with the central end of a segment split from the unaffected nerve.

2. Lateral anastomosis of the peripheral segment of the affected nerve with the unaffected nerve.

3. Lateral anastomosis of the central end of a segment split from the unaffected nerve with the diseased peripheral nerve.

4. End-to-end anastomosis of both central and peripheral ends of the affected nerve with the split segments of the unaffected nerve (Basil Kilvington).

5. Lateral anastomosis of one or more muscular branches of the affected nerve with the unaffected nerve.

I have never had occasion to use the last two methods, but I feel that the first, or end-to-end anastomosis of split-off segments of the two nerves, promises the best results, as closer union may be obtained, and it is more favorable to the rapid growth of new axis-cylinders into the peripheral stump. The majority of surgeons seem to be agreed that it would be unjustifiable to divide entirely the healthy nerve as advocated by Basil Kilvington.

Operative interference with the nerves should never be attempted for at least a year after the onset of the paralysis, so that the muscles which are only temporarily affected may have time to regain their power and tone. During this time massage, electricity, baking, and active and passive motions are of the utmost importance. These latter therapeutic measures are most essential to the after-treatment of all cases in which nerve-grafting has been done, and good results are not to be expected if they are not persisted in faithfully for a long time.

The question of suture material is an important one, but it seems to be the general consensus of opinion that the best results are obtained with some form of animal suture, though white silk has its distinguished advocates. I prefer fine catgut, either plain or carbolized. In making the anastomosis as few stitches as possible to obtain close coaptation should be taken, and these should pass through the nerve sheath only and not through the trunk of the nerve. The best procedure is to pass two sutures through the sheath on each side of the point

where the nerve is to be divided, and using these to raise the nerve with, cut between them with a sharp knife. In this way unnecessary handling of the nerve and the use of forceps are avoided, which is most desirable. The use of scissors in dividing the nerve is to be strongly condemned, as they bruise the fibers too extensively.

As stated elsewhere the reported cases of infantile paralysis in which neuroplasty has been employed are very few. Peckham of Providence, R. I., who, so far as I can ascertain, was the first to use it in this country, reported a fairly successful case in 1898, and a second one some time after. James K. Young of Philadelphia, Frazier, Hackenbruch, Harris and Low of London, and R. T. Taylor of Baltimore have all reported cases of infantile paralysis in which nerve anastomosis was followed by marked improvement, in one or two instances approaching cures. In 1907 Babcock of Philadelphia reported a most interesting case of brachial palsy following anterior poliomyelitis, his operation being by far the most elaborate of its kind that has come under my notice. Briefly, he divided the diseased sixth cervical nerve high up on the right side, and after isolating it as far downward as possible, united it end to end with a bundle of nerve fibers split from the sixth cervical on the left side. In making the anastomosis a passage was tunneled from side to side between the anterior muscles of the neck and the trachea, and the ends of the nerve bundles were then united through an incision just above the suprasternal notch. In this way new nerve paths were formed from the healthy left brachial plexus to the paralyzed right. Three and a half months after operation there was not only marked improvement in sensation and development, but there was some power of voluntary motion, and the chances are good for a complete recovery.

The two cases operated on by R. T. Taylor, and which the writer in his capacity of Resident Surgeon at the Hospital for Crippled Children of Baltimore, had every opportunity of studying, were both extensively paralyzed, one being a paraplegic. The improvement in these cases, while not as great as we had hoped for, was still sufficiently marked to encourage us to proceed along the same lines, and we subsequently operated on two other cases, confining ourselves, however, to monoplegics.

In the last year and a half the writer has operated on three cases of infantile paralysis, one nearly a year ago and the other two about three months ago. These latter I will take up in a subsequent report, but it may not be amiss to mention here that at an examination made two days ago (March 31) there were distinct signs of returning sensation and power.

Case I.—A. B., aged ten years. First seen April 22, 1907. The father and mother are strong and healthy; one sister has a paralytic talipes valgus, and another paralytic talipes equinovarus. Four other brothers and sisters normal. The child was perfectly healthy up to four years ago. Breast-fed twelve months; walked and talked at fifteen months; teething normal. Had whooping cough at two years of age and measles about a year later. No other diseases of childhood.

The present illness began in August, 1903, during a very hot spell. The child went to sleep near a window in the afternoon and the same night had high fever and vomiting; he complained of severe headache and photophobia, and other meningeal symptoms were marked. Symptoms lasted about a week, and he was out of bed in ten days, but could not use the right leg. This has improved so that the boy can walk, but he limps badly and drags the right foot, which is turned in. General condition is good, appetite and bowels are normal. There was never any paralysis of the excretory organs. Physical examination shows a good general condition. He is a strong, well-nourished child. There is slight right talipes equinovarus, the equinus element being most marked; the foot cannot be manually corrected on account of the strongly contracted tendo Achillis. The peronei seem to be the only muscles affected and the boy cannot abduct or dorsally flex the foot. There is no response to the slowly interrupted faradic current along the distribution of the peroneal nerve. Nerve transplantation advised.

Operation, April 29, 1907. An incision was made over the biceps tendon and the external popliteal nerve was exposed and partially divided between sutures. A longitudinal incision was also made in the nerve extending above and below the transverse incision, thus isolating a small bundle of fibers above and below. A similar procedure was gone through with on the internal popliteal, the dissection being made close to the bifurcation of the sciatic. The central segment of the internal popliteal was then sutured to the peripheral segment of the external popliteal with fine carbolized catgut, an end-to-end anastomosis being made. In the same way the central stump of the external was sutured to the peripheral stump of the internal popliteal, making a crossed transplantation. The skin was closed with a subcutaneous silver wire stitch. At the same time the tibialis anticus, tendo Achillis, and plantar fascia were divided subcutaneously, and the whole limb was put up in a plaster cast.

The skin wound healed by first intention, and six weeks after the operation the cast was removed and an ankle brace with inside upright was substituted. There seemed to be no improvement in the function of the limb at this time, though the position was much better. From this time on a strict course of electricity, baking, and massage was persisted in, with the result that at the end of four months the foot could be slightly abducted and dorsally flexed, and there was distinct response to faradic stimulation. The treatment, in carrying out which the writer was faithfully seconded by the child's parents, was continued, so that at the present time the motions of the foot have returned to such an extent that the child can walk without the brace and put the foot squarely on the ground. Abduction and dorsal flexion are quite forcible, and response to faradic stimulation is pronounced. The brace is still being worn for protection and the other treatment carried on as heretofore. Since the operation the leg has increased one-quarter of an inch in size.

In conclusion the writer wishes to express his firm conviction that to nerve anastomosis we must look for the most beneficial results in many cases of infantile paralysis—results which can never be obtained from the other operative measures now in use, and which will be the means of converting into useful citizens many little sufferers who otherwise would be doomed to lifelong dependence on crutches or braces, burdens to themselves and to the community.

INSANITY; ITS GENESIS AND TRANSMISSIBILITY.

By SAMUEL WESLEY SMITH, M.D.,

NEW YORK.

Though cases of insanity are not unknown among savage races, they are so rare under such primitive conditions of humanity, that we would be safe in assuming them to be diseases of civilized life. As barbarous communities advance socially, insanity keeps pace with the progressive development.

An interesting question arises in this connection: "What part does heredity perform in the production of insanity under such circumstances?" So far as known, insanity did not exist at all, at any time in the history of those races, unless in exceedingly rare and isolated cases, which can hardly be admitted as factors in producing the results stated. Consequently, the conclusion is forced upon the mind that hereditary influence had little or nothing to do with the causation of insanity among people who were rising in the scale of civilization. It is reasonable to assume that there was a time when insanity did not exist, and that when it finally did appear, heredity was not a factor in its production. Such an original condition of humanity free from the taint of insanity, would, as a hereditary influence, be much more powerful in perpetuating the normal type, than any subsequent disease would be in deteriorating it permanently. Nature is constantly striving towards the elimination of disease of all kinds, towards the removal of all defects, mental or physical, and this recuperative, restorative agency would tend to counteract and ultimately remove them from the organism.

Assuming that the insane diathesis is conveyed to the progeny, sometimes to manifest itself without a break in the continuity, at other times, intermittently, there is transmitted at the same time a primary restorative force which makes its presence felt, not intermittently, but constantly and continuously.

Many diseases are productive of a disturbance of the mental faculties, which either from their being associated with the course of a particular disease, or from their slight intensity, are not included under the head of insanity proper. But it should not be forgotten that those temporary impairments of the mental equilibrium may and probably do in the majority of cases, so affect the mechanism of mind that individuals may become really and permanently insane through the operation of causes which would not injuriously affect them at all but for the previous trouble. Occasionally, however, a disease may produce a permanent impairment of the thinking apparatus, and the person become incurably insane, without a possible suspicion of heredity having anything to do with the genesis of the disorder.

There is a general position taken by the members of the medical profession that a constitutional condition may be developed in a family, which, although it may never manifest itself in a concrete form as disease, may materially influence development, decrease the power of combating disease, or make itself felt in a more subtle manner by a mere tendency to degenerative changes. In this way, it is supposed, hereditary predisposition may be a common factor in all insanities—in the congenital class as an arrester of brain development, in the acquired as a producer of the nervous diathesis.

Personally, I do not think we should travel so far afield in tracing the origin of the great majority of cases of insanity.

In most cases, the causes producing aberrancy of mind are limited to the individual. The parents, or others more remote in the family line, probably had sins enough to answer for, without being held responsible for either the actions or condition of their crazy descendants. Vicious habits of youth and even of those of more mature age; excessive indulgence in the use of ardent spirits and narcotics; the mad rush for wealth and social distinction, and other salient features of our complex civilization are almost wholly responsible for furnishing patients for our institutions for the insane.

Despite those adverse features of our civilization, which tend to impair us mentally and physically, I do not think that the proportional increase of the insane is such as to cause any uneasiness. If there is an increase at all, it is more apparent than real, and is probably due to the fact that many are now sent to institutions for the insane who were previously cared for at their homes. I imagine that this class of the deranged would stand a better chance of recovery at their homes, or in smaller institutions, than in some of our overcrowded State Hospitals for the insane.

To digress for a moment, I desire to say that in eight or nine of our largest and best equipped State Hospitals for the care of the insane, there were on September 30, 1906, 1922 patients in excess of their architectural capacity. To obviate this condition, I will repeat what I had to say to the State Association of Superintendents of the Poor at Plattsburg in the autumn of 1888:

"Inasmuch as the State has failed in the past to keep pace with the natural increase of the insane, I fear we will again find our State Institutions overcrowded as in 1877. After twelve years' experience in the exclusive care of the insane a return to county care of the chronic insane became imperative. Believing, as I do, that history *will* repeat itself, I would suggest a plan which I believe ought to meet with the approval of those interested in the proper care and maintenance of those unfortunate and helpless wards of the State. It is this: That when it becomes evident that State institutions for the insane were overcrowded and caring for a number of patients beyond their architectural capacity,

the Board of Supervisors of any county so desiring, should be authorized to purchase ground and erect buildings with an architectural capacity of twenty to thirty per cent. in excess of the number of insane in the county. When such buildings have been erected and approved by the State Board of Charities, or other authority, and accepted by the State, the State should pay to the county one-half of the cost of the building, provided the total cost did not exceed $300 per capita. The Governor shall appoint three trustees and the Board of Supervisors of the county two trustees for the government of said institution, said Board to have entire management of the institution as exercised by the Boards of Managers of State institutions for the insane."

One would imagine that peaceful, uneventful lives, passed amid surroundings conducive to repose and peace of mind, would be comparatively free from aberrancy of mind, as compared with the cities. Such, however, is not the case, and though the proportional number of the insane is larger in the large cities than in the rural districts, there are various factors which enter into the calculation, so far as the city communities are concerned, which, when considered, make us wonder that the proportion of insane in the country should have been so large, when causes of excitation were so few.

A well-known alienist of New York, in an article published recently in a leading New York newspaper, wrote as follows: "The great factor in determining insanity is heredity, and I might say it is also the causation of most other nervous diseases." This alienist quoted Ribot as defining heredity to be "that biological law by which all beings tend to repeat themselves in their descendants. By it the groundwork remains unchanged amid incessant variations."

While I do not wish to minimize the effect of heredity as an agent in the transmission of either mental or physical tendencies and qualities, I believe that many attribute entirely too much to it in determining the conditions of mental and physical life.

The alienist quoted cites a passage from the Bible in support of his views, and would have Moses, or whoever wrote it, stand sponsor for his extreme position on the subject of heredity. The writer of the sacred text in declaring that the sins of the father shall be visited upon the children unto the third and fourth generation, had reference, in my opinion, to the imputation of moral guilt, with its consequences to the progeny, not to the transmission of any taint, mental or physical, in the way of heredity.

The same contributor, apparently endeavoring to fortify his views relative to the universality of the operation of the law of heredity, advances the claim in its behalf that genius and extraordinary talent of any kind are striking confirmations of this law, and cannot account otherwise for "the lives of our three martyred Presidents, Lincoln, Garfield, and McKinley." Had the writer ever read Grey's Elegy, he would have, I think, held a different opinion. The poet's speculations upon the possibilities of some human lives passed under different circumstances, are juster and more philosophical than these. The poet shows how some "mute, inglorious Milton," "noble Hampden," or a "Cromwell guiltless of his country's blood," lacking opportunity, lived and died obscure, and was buried in a nameless grave in that country churchyard.

When the adverse circumstances under which many live in the large cities is considered; when we bear in mind the temptations which lure to excesses of various kinds in them; when we think of the din, the tumult, and the mad rush, the tension of brain and the excitement of mind, the marvel is that there should be so few insane in the city, and so many in the country.

There is another factor in our modern city life, especially in our city of New York, which has an important bearing upon this question of insanity. The large numbers of foreigners living here, many under conditions not conducive to health of either body or mind, their homesickness and loneliness, doubtless furnish a larger proportional number of the deranged than the rest of the population do. Probably many arriving here as immigrants carry the germs of mental and physical disease with them, while it may be that some are permitted to land who are really insane.

An article on "Psychopathic Rulers" by Dr. Allan McLean Hamilton, appeared in the March number of the *North American Review*. In its wholesale denunciation of ruling families, ancient and modern, it is worthy of the most ultra of socialistic propagandists. The author refers to the insane Cæsars, but in my reading of history I never became aware that any of the Cæsars were insane. The first of them, Julius Cæsar, great in various departments of human activity, was a genius, which, I presume, would include him in the category of the insane, according to the theories of Dr. Hamilton and Prof. Lombroso. Cæsar Augustus, one of the best of the Roman Emperors, the nephew of Julius Cæsar, was without doubt one of the sanest of men, and Nero, the last Emperor of the Julian family, began life as a model young man and then, as sometimes happens even in our days, he cut adrift and became desperately wicked. No one, however, unless a New York insanity expert, would have adjudged Nero insane. He was radically bad, and that was all the dementia about him. Further on the doctor writes: "The careful investigation of some such line, for instance as the Bourbons, will disclose widespread degeneration, and it is known that one notable lunatic, 'Joanna the Mad,' was responsible for much of the moral and intellectual Bourbon decay. Her great-granddaughter, Marie de Medici, married Henry IV of France, and the progeny immediately presented the taint of insanity, which subsequently cropped out very extensively in the French and Spanish line." This statement is absurd. Henry IV, the first of the Bourbon line, known to history as "the great and good King," was no saner than his wife Marie de Medici. Their grandson, Louis XIV, the "Grand Monarque," gave no evidence in his life and conduct of being tainted with insanity, nor am I aware that any of his descendants, good or bad, were insane.

Our proscriptive alienist does not believe in half measures, and he includes the Hapsburgs, the Oldenburgs, the Romanoffs, the Stuarts, and the present reigning family of Great Britain in his category of psychopathic rulers. The family of Hapsburg is represented by the present Emperor of Austria-Hungary and none but the boldest of alienists would even dare to insinuate that the venerable monarch who has ruled so sanely and justly for a long term of years is anything else than the most rational of men. The present Emperor of Russia is of Romanoff-Oldenburg stock. Neither he nor his father nor his grandfather could possibly be regarded as insane in any particular. Catherine II and her son Paul were not estimable individuals in any respect, but their malady was moral, not mental, and their cruelty and viciousness were the result of a bad heart, rather than a deranged mind.

Regarding the Stuarts, the writer quoted says: "The mental instability of the Stuarts in England is well known." I never knew before that the Stuart kings were fit subjects of inquiry by a lunacy commission. How the "Scottish Solomon," James I, would smile if informed that the court physician doubted his sanity. Charles I, his son, was arbitrary and had too high an opinion of the kingly prerogative, but though he lost his crown and his life in consequence of his despotic notions, he was all his lifetime as far as possible removed from a suspicion of suffering from a mental derangement. James II, the last of the Stuart Kings, would be without doubt regarded by the writer of "Psychopathic Rulers" as the craziest of all the Stuarts for, did he not, as they said at the time, "sell three kingdoms for a mass"? Men before then and since have sacrificed their lives as a matter of principle and for conscience' sake, and right-thinking men have called them patriots and martyrs. James II sacrificed a triple crown for his faith—an act which certainly does not presuppose weakness of mind or instability of any kind.

Again Dr. Hamilton remarks, "The weakness and profligacy of the Georges, who were more or less deranged, were notorious.... Queen Caroline was more insane than her foolish and dissipated husband, and it was only when the Saxe-Coburg blood was infused that it neutralized that which was synonomous with degeneracy, and with the accession of Victoria a new order of things was established to the great good of the English nation." This statement is not only misleading, but is also incorrect. So far as the Georges were concerned George III was the only one that displayed any symptoms of mental disorder and this, most certainly, was not due to any hereditary taint. Queen Caroline was sufficiently wronged during her lifetime, without being villified after death.

But to come nearer home our alienist sounds a note of alarm which, though introduced with all seriousness, can scarcely fail to make sensible people smile. He tries to show that there is a grave danger threatening the country, the possible election of a psychopathic President. The President of the United States is invested with such a degree of power, that, in the opinion of Hamilton, it might prove disastrous to the country were a psychopathic chief magistrate elected. While he does not suggest that candidates for the Presidency should be examined by a lunacy commission, he thinks the country should have some guarantee as to the mental soundness of candidates for that high office.

LACTIC ACID BACILLI CULTURES IN NOSE, THROAT, AND EAR WORK.

By H. HOLBROOK CURTIS, M.D.,

NEW YORK.

The positive results obtained from the use of the lactic acid bacilli in the digestive tract, after the Metchnikoff method, have led me, at the suggestion of Dr. Chas. E. North, to experiment in the respiratory passages with cultures of Massol's bacillus, obtained from the Lederle laboratory. While it was with a certain amount of skepticism that the experiments were begun, the good results in certain cases have been so marked that the conclusion seems warranted that a very valuable advance has been made in the treatment of pathogenic conditions of the nose and the accessory cavities by the use of the lactic acid secreting bacilli.

In the test cases, we examined the secretion from the nasal fossæ before the bacilli were introduced, and again after successive applications of the culture. In some cases after a limited number of injections not only have the pyogenic bacteria been destroyed, but there has been found a total absence of all bacteria in the secretions.

Injections by means of a catheter into a profusely discharging frontal sinus have caused a diminution of the discharge, amounting to ninety per cent., after the second dose of a cubic centimeter of the culture; and this in a case of over a year's duration. In several instances of chronic ethmoiditis with profuse postnasal discharge, the condition has been so relieved that the patient has asserted himself entirely cured.

Of especial benefit it seems to be in the treatment of the early stages of atrophic rhinitis. In these cases the crusts liquefy and the nose presents an entirely different appearance after two or three applications. It is too early to state that there has been an actual cure in any of these cases, but the evidence has been so strong that it would seem to point to ultimate good results. I have no hesitation in saying at this stage that there is no topical application which approaches in any manner the efficacy of the lactobacilli culture in the treatment of mucopurulent secretion from the nose.

Should future experimentation substantiate the evidence of results obtained thus far, it would seem that a new era in the treatment of pathogenic bone cavities has been instituted—and that the theories of Metchnikoff admit of a much wider application than he has claimed. What will be the success of this treatment in suppurative chronic otitis media remains to be seen. As it is my intention to speak from a clinical and not from a bacteriological point of view, I will further on cite a series of cases which have been under observation during the past month, and postpone absolute conclusions as to the real value of the treatment until such time as other observers have verified the almost specific virtue which the culture seems to possess. The method of application has been as follows: In the nasal cavity a cubic centimeter of the culture broth has been sprayed under pressure on either side of the middle turbinate, in order to reach the anterior and posterior cell orifices, the theory being that the bacilli will find their way into the ethmoid cells and the accessory cavities, and by their secretion destroy the pyogenic bacilli which are causing the disease. A sterilized narrow test tube into which has been poured a cubic centimeter of the culture admits a sterile Sass spray tube and makes the application of the medium by compressed air pressure very convenient. In the sphenoid, frontal, and maxillary sinuses the culture may be syringed through the metal catheters appropriate to the locality. It is too early to state what improvement, if any, may be expected from this treatment in cases where there exists necrosis of the bone, but where the disease is confined to a pus-secreting membrane in the accessory cavities, it promises most excellent results.

The treatment of the cases cited below has been as follows: The nose is cleansed by sterile water or a mild saline solution, no antiseptic being employed. If a sinus is injected, or the meatus sprayed, the patient is directed not to blow the nose for an hour or two and to employ nothing as a spray or douche until the following day, when a mild saline solution may be employed if imperative, for cleansing purposes.

The cases now under observation are treated

every second or third day. The element of suggestion in the cases reported in this paper has not been eliminated, as it was considered necessary to obtain the patient's consent before experimenting; but, as it has been demonstrated that no bad results can occur, provided the proper precautions are taken, in future the patients under observation will not be aware of the nature of the application.

Case I.—Banker, age 56. Has suffered for twenty years from profuse postnasal discharge. Right frontal sinus affected. Operated upon from within in 1905 and douched. All the ethmoidal region involved. Pain in frontal region and headache a constant factor. Douching does not now reveal presence of pus in frontal sinus. Constant hawking disturbs sleep at night. The nose was cleansed with distilled water, and sprayed as described into the middle and superior meatus. The first treatment was given May 12. On the 13th the discharge was thinner, 15th much less, 17th very much less and pain gone, on the 22d there was no discharge containing pus and there had been no pain. June 4, conditions seem normal. Patient says he is practically well—never dreamed of such comfort. June 19, no recurrence of pain or discharge.

Case II.—Mr. S., age 60. A year ago came from Brooklyn with empyema of right frontal sinus. Tip of middle turbinate removed and sinus catheterized and douched. Pain was relieved, but discharge though much diminished, never ceased. May 16 injected one cubic centimeter of the culture through a catheter into the sinus. May 18 repeated treatment. May 24, reports discharge diminished 75 per cent. June 4, son called and reported discharge entirely stopped.

Case III.—Mr. G., age 54, lawyer. Has suffered from chronic suppurative ethmoiditis with profuse postnasal dropping for many years. Removed a spur and cauterized turbinates. May 14, 18, 22, and 24, sprayed nose, not yet healed, with the Massol bacillus culture. Patient reports that the second application diminished the discharge 75 per cent., the fourth proved even more efficacious; all hawking stopped. "No more discharge than natural." June 18, patient continues free from morning accumulation in throat and has no mucopurulent discharge.

Case IV.—Miss C., age 25. Lymph node appeared in neck a year after the removal of a chain of glands. In operating for removal, the sac was ruptured, and the cavity was curetted and syringed with lactobacillus culture. The wound closed up in a week; no drainage after the first day.

Case V.—May 15. Child, 9 years. Incipient atrophic rhinitis. Thick crusts around vestibule and inferior meatus full of mucopurulent secretion. Sprayed every day for two weeks with the Massol culture. From the first application softening of the crusts was noticed. The flecks of slate colored material on the middle turbinates disappeared. Discharged apparently cured June 18.

Case VI.—Child, 11 years. Same general conditions as in Case IV. Atrophic rhinitis. Nurse has offensive ozena. Commenced treatment May 16 and has continued four weeks. The child is reported as being very much improved, being entirely free from "scabs." The nurse who has been using the same treatment, viz., a daily spray of Massol bacillus culture, says the crusts are dissolving; it is very easy to blow them out. Does not have to use swabs and douches. No odor. Both cases report marked improvement. Sailed for Europe June 13.

Case VII.—Antrum and frontal sinus empyema of the left side. Woman, aged 25. Cause, grippe infection in December last. Removed first molar and syringed antrum daily with antiseptic douches. Delayed radical canine fossa operation, hoping to avoid it by conservative methods. A brown and unhealthy pus clot as large as a nickel five-cent piece was constantly found in the antrum washing. On May 20 an injection of 1 c.c. lactobacillus culture was begun every other day. Discharge changed at once, the brown pus gave place to a lighter yellowish flocculent discharge which did not sink to the bottom of the dish. Frontal sinus could not be douched owing to deflected septum and impossibility of entrance within. Nose was sprayed. June 8 patient reports great improvement. June 20, frontal sinus has been constantly improving under home treatment with the Massol bacillus culture in an adrenalin atomizer, until to-day there is no pus in nose; antrum is practically well. Only three injections were given in antrum.

The histories of the above cases seem to me to be in themselves a sufficient apology for what might appear a somewhat premature announcement.

118 Madison Avenue.

SOME CASES, OTHER THAN OBSTETRICAL, IN WHICH HYPODERMATIC INJECTIONS OF ERGOT HAVE BEEN OF GREAT SERVICE.

By E. P. ROBINSON, M.D.,

NEW YORK.

Dr. Alfred T. Livingston, in the *Journal of the American Medical Association*, March 21, 1903, and in the Medical Record, November 23, 1907, has dealt with the uses of ergot in a very able manner. I am in absolute accord with his general deductions given in the latter article, and which, for the benefit of those who have not read that article, I take the liberty of reproducing. Dr. Livingston says: "The general deductions that appear to be warranted, from my personal experience with the therapeutic application of ergot, are: (1) That its direct and specific effect is the contraction of unstriated muscular fiber, or other involuntary contractile tissue. (2) That it does not markedly contract that which is normal in tone; but (3) That it is emphatic in its contraction of that which is lacking in tone, and (4) That it is prompt and striking in such effect, in proportion to the recency of occurrence of the atonic state in such fiber. (5) That its widest field of usefulness is its application to the muscular coat, or other contractile tissue, of weak and relaxed blood-vessels. (6) That it there tends to equalize vascular tension; to distribute the blood equably throughout the body; to restore or to promote functional activity of glands and organs generally, and vasomotor centers particularly. (7) That it is useful to restore tone in the unstriped fiber of the walls of the hollow viscera, stomach, bowels, bladder, uterus, etc. (8) That the prevalent, popular notion, existing even in the medical profession, that it is a dangerous drug, and likely to produce ergotism, is unfounded as regards the modern pharmacopial preparations, at least as regards such as I used during the past thirty-four years. (9) That its local action upon the stomach is often offensive, especially if full doses are given; that its absorption from the stomach is uncertain, both as to promptness and degree; and, therefore, (10) That its administration should be limited as much as possible to hypodermic injection, which assures immediate effect, admits of exact regulation of dose,

and avoids nausea and other ill effects of its administration per os."

As I recognize that the therapeutic application should be more extensively employed by my fellow practitioners, I therefore, submit three typical cases out of a series of several hundred in which I have employed intramuscular injections of ergot with very happy results. This method of treatment will be found of great value in pathological conditions of the blood-vessels and therefore of especial service to the skin specialist. During the past seven years I have used it in over three hundred cases of acne rosacea with gratifying results in every case. It is my belief that the staphylococci will not attack a portion of the body unless there is first a sluggish flow of the blood due to an atonic condition of the muscular coat of the blood-vessels, rendering that section of the body a ready prey to bacterial invasion. The effect of ergot is to tone the muscular coat and so maintain an even, steady flow of blood. An old method, and one still employed, of treating some stubborn cases of acne was scarification, which was usually followed by unsightly scars. In the use of ergot hypodermatically we have a more efficient remedy and the complete elimination of the possibility of scar formation. It is needless to say that in addition to ergot the use of ointments and washes locally should not be neglected, as they materially aid in eradicating the infection.

The ergot should be injected deeply into the muscles, preferably the gluteal region. The frequency of the injection varies with the condition of the patient. I have usually given injections on alternate days. There is a decided objection on the part of some physicians to the use of the hypodermic needle. I believe this to be quite unwarranted, as I have personally administered upwards of forty thousand injections in the correction of various facial deformities, specific diseases, and other conditions without untoward effects, but with definite therapeutic results.

Case I.—M. S., male, aged fifty-six, sells newspapers, greatly addicted to the use of alcohol; had a very severe case of acne rosacea. His face was entirely covered with the eruption and he had the characteristic red nose that accompanies indulgence in too large quantities of mixed ales. Injections of ergot were administered on alternate days until in all six injections were given. As a result of the first injection an ecchymosis took place. This merely goes to show that the blood-vessels were extremely atonic. After the second injection there were no following ecchymoses. The result of these injections was the complete cure of the condition, and now, at the expiration of two years, there has been no semblance of a return, even though the patient still continues to drink his usual amount.

Case II.—L. A. B., female, aged about sixty, very fat, weighing over two hundred pounds, treated seven years ago for varicose veins of the right leg by injections of ergot every other day until seven injections were given. Although the veins are not normal, the current of blood is quite good even at this late date. In this case, after the third injection I discontinued the use of the bandage and up to the present time it has not been necessary to replace it.

Case III.—G. P. W., male, aged thirty-five, commercial traveler, greatly addicted to the use of cigarettes, but temperate in other respects; he smokes several packages of cigarettes a day, and is very nervous, so much so, in fact, that he could not write an order properly. I endeavored to persuade him to give up smoking but without success. On examination I found his venous circulation far from perfect. The veins were engorged and the flow of blood sluggish. After five injections on alternate days the nervousness had entirely disappeared and at the same time the desire for cigarettes had ceased. A year later he again began the use of tobacco in this form but more moderately, and thus far there has been no return of the nervousness.

Sugar.—Sugar is often given a bad name from a physiological standpoint, but in many instances it is questionable whether it is deserved. It seems inconceivable that the bountifulness with which the world is supplied with sugar should mean anything else than that it is designed for human food. Sugar is one of the most powerful foods which we possess, as it is the cheapest, or, at any rate, one of the cheapest. In muscular labor no food appears to be able to give the same powers of endurance as sugar; and comparative practical experiments have shown without the least doubt that the hard physical worker, the athlete, or the soldier on the march is much more equal to the physical strain placed upon him when he has had included in his diet a liberal allowance of sugar than when sugar is denied to him. Trophies, prizes, and cups have undoubtedly been won on a diet in which sugar was intentionally a notable constituent. It has even been said that sugar may decide a battle and that jam after all is something more than a mere sweetmeat to the soldier. The fact that sugar is a powerful "muscle food" accounts probably for the disfavor into which it falls, for a comparatively small quantity amounts to an excess, and excess is always inimical to the easy working of the digestive processes. A strong solution of sugar is irritating to the tissues, will set up superficial inflammation, and may produce a form of eczema. It is well known that an excessive diet of sugar irritates the mucous membrane of the stomach and encourages the production of mucus and of a highly acid gastric juice. The ingestion of much sugar spoils the appetite. Children who have been tempted to overindulge in "lollipops" between regular eating times do not want their ordinary meal. The schoolboy spoils his dinner by eating too many sweet things before that meal. An overindulgence in sweet liqueurs, in sweet ices, and in "crystallized" fruits after dinner retards the digestion of the meal. Sugar satiates; it is a concentrated food. Where sugar does harm, therefore, it is invariably due to excess. Taken in small quantities and distributed over the daily food intakes sugar contributes most usefully in health to the supply of energy required by the body. In certain diseases, of course, the presence of sugar in the diet is plainly undesirable. Generally speaking, however, there is a prejudice against sugar which is not justified by physiological reasoning—at all events, when it is eaten in moderation; and it is a curious fact that the man who practically abstains from sugar, or reduces his diet to one almost free from carbohydrates in favor of protein foods such as meat, often shows feeble muscular energy and an indifferent capacity for physical endurance.—*The Lancet.*

Typhoid Fever and Descending Infection of the Biliary Passages.—A. Lamierre and P. Abrami have made experiments in animals and observed cases in human beings which show that the old accepted belief that typhoid infection of the biliary passages was always an ascending process is erroneous. They find that the infection is a descending one, the typhoid bacilli entering the bile passages from the blood and thus causing suppurative lesions of the gall-bladder. The bacilli are eliminated by the liver and the system may be protected against the action of these germs by this elimination which carries the bacilli away from the system.—*La Presse Médicale.*

THE FIGHT AGAINST UNCINARIASIS IN PORTO RICO.

The colonial possessions of the United States have brought with them many new medical as well as economic and political problems. The dysenteric diseases of the Philippine Islands, the yellow fever of Havana, the endemic anemia of Porto Rico have all been carefully studied since the Spanish-American War has placed the responsibility, permanent or temporary, for the health of the inhabitants of Cuba, the Philippines, and Porto Rico in the hands of the American medical profession, and the work of Strong in Manila, of Findlay in Havana, of Ashford and King in Porto Rico has been wonderfully productive of results. Yellow fever is no longer endemic in Havana, the Philippine studies have added much to our knowledge of the pathogenesis of diarrhea, and Dr. Ashford's announcement that the anemia of Porto Rico was due to a parasite, which was classified later by Stiles as *Uncinaria americana*, opened a way to the successful fight against this condition which was causing untold economic losses to the island. In a report of the permanent commission for the suppression of uncinariasis ("Anemia in Porto Rico"), this work is given in detail. Omitting the particulars in regard to the attempted education of the natives by various instructing circulars and posters, we find, in the results of the work, that 89,233 were treated for uncinariasis during 1906 and 1907, these patients making some 500,000 visits to the stations established by the commission. In all of these, microscopical examination of the blood and of the feces was undertaken, making the diagnosis positive. Then thymol and betanaphthol were administered as specifics for the disease, a purgative of sodium sulphate being given before and after the medicine. As a result, 25.71 per cent. of the patients were cured completely; 17.38 per cent. were "practically cured," having received four doses of the medicines which probably resulted in the expulsion of over 96 per cent. of the parasites; in 16.20 per cent. the condition was bettered; 40.50 per cent. are still under treatment, and only 0.21 per cent. died during the two years.

Much valuable information has been collected by the commission in regard to the symptoms and pathology of uncinariasis. Of course, in a country where 90 per cent. of the working population harbor the parasites of the disease, the cure of several thousand persons is only a step toward ridding the country of the plague. The commission, therefore, recommends that at least fifty permanent stations be established for the treatment of the disease; that a campaign of education should be carried out teaching the inhabitants to avoid spreading the disease by sanitary disposal of all excreta; that legal measures should be adopted, enforcing the wearing of shoes by all laborers employed by the government, who should, moreover, be employed only on presentation of a certificate showing them free of the disease in question. The commission says properly that such regulations, although appearing to threaten the personal liberty of the citizen, in the end will benefit both the individual and the whole society of the island.

NATURE AND TREATMENT OF LEUKEMIA.

The primary diseases of the blood constitute but a lately opened chapter of human pathology, yet they have formed a subject of such interest both to the research workers and to the practical clinicians that their symptomatology and the pathological changes occasioned by them in the human organism have received much special attention. The cause of them, however, has remained undiscovered, and the treatment has been very inefficient. It may be assumed that parasitic etiology is improbable, since the attempts of Mosler and Bollinger to infect susceptible animals by the leukemic blood were completely unsuccessful, and like experiments carried out by Schupfer with patients suffering from incurable carcinomatous disease could produce no leukemic changes. Most interesting findings in regard to the pictures of the blood seen in leukemias have been lately published by Grüneberg (*Medizinisch-naturwissentschaftliches Archiv*, Volume I). His examinations of embryos has shown that human embryonal blood answers completely to the picture of lymphatic leukemia, and even the increase of normoblastic red cells after the sixth month makes the blood quite comparable to the conditions found at certain stages of the disease when compensating processes seem to be most evident. The essence of the leukemias, therefore, is the return of the blood to its embryonal composition so far as its cellular elements are concerned. In an article in the *Berliner klinische Wochenschrift* for June 15, 1908, Grawitz indeed says that in many occasions the leukemia is nothing but the unlimited attempt at blood formation which has been called forth by some such cause as chronic inflammatory and suppurative conditions. Ziegler and Tochmann have published a case in which a simple neutrophile leucocytosis of 28,000 leucocytes called forth by a chronic staphylococcus infection changed to a leucocytosis of 240,000 cells, mostly myelocytic in character.

Grawitz reports the success he has had in the treatment of leukemias during the last three years, that is, since the *x*-rays have been utilized for this purpose. Ten of the twenty-six patients suffering from myelogenous leukemia recovered under treatment with the rays, the spleen diminishing to normal size, and the blood assuming its usual picture. Three of the ten had relapses, but a second course of treatment again proved efficacious in curing them. Only one patient with lymphatic leukemia was cured of the disease, if freedom from the signs

of the affection for the period of two years constitutes a cure. In general, this type of the disease proved quite refractory to the *x*-ray therapy. However, up to the introduction of this treatment, the outlook for all leukemic patients was very dark indeed. If one type of the disease even can be successfully controlled, it means that a great many victims may be annually saved. It seems probable, too, that early diagnosis and the improvement of the technique of treatment will increase the percentage of the cures.

OPHTHALMOVASCULAR CHOKE.

Derangement of function in any given organ is rarely unattended with manifestations referable to other organs as well, and there is sometimes danger that the underlying disorder may be overlooked by reason of the obtrusiveness of the secondary phenomena. It has come to be recognized pretty generally that eyestrain due to refractive error or muscular imbalance is responsible for a number of distressing and obscure symptoms, speedy relief from which has been afforded by proper correction of the ocular abnormality. There are, however, not a few instances in which visual discomfort persists in spite of the most careful and expert treatment. Some of these, no doubt, are related to incorrigible defects of accommodation. Others, it would seem, may be traced to local circulatory conditions characterized by interference with the intraocular blood-supply.

For one group of the latter, Dr. G. M. Gould (Bulletin of the Johns Hopkins Hospital, April, 1908) proposes the term ophthalmovascular choke, and he reports ten illustrative cases. In the ramification of the retinal arteries and veins some of these vessels come to lie upon and compress others, thus preventing proper ingress and exit of blood. As a result, the nutrition of the parts must eventually suffer some impairment. Ophthalmoscopic examination not rarely discloses tortuosity, distention, pulsation, and flattening of retinal vessels. Subjectively, a characteristic symptom is the so-called fading image, a term that appears sufficiently self-explanatory. In some instances attacks of fainting or swooning have been observed, and also a peculiar type of photophobia.

Therapeutically, relief can be obtained only by abstention from use of the eyes. Massage of the globes has been employed without success. Gould suggests the use of long-continued instillations of a weak solution of eserine. Perhaps the administration of nitroglycerin or some other form of nitrite might prove useful. It seems not impossible further that other well-known ocular disorders may have their origin in the circulatory disturbances under discussion.

The Value of a Differential Leucocyte Count in Acute Appendicitis.

The question of the value of a differential leucocyte count in acute infections is still the subject of considerable difference of opinion. Sondern, who has done much work along this line, attaches great value to the differential count as an aid in diagnosing the gravity of infections, claiming that the relative number of polynuclear cells is an indication of the severity of the toxic absorption. Recently A. H. Noehren (*Annals of Surgery*, February, 1908) has furnished additional data on this subject. They are based on the examination of the blood in sixty cases of acute appendicitis just before operation, which made it possible to compare the count with the actual condition present. His statistics included cases of diffuse purulent peritonitis, gangrene of the appendix, localized abscess, and inflamed appendix without adhesions. He found that in every case with ninety or a higher percentage of polynuclear cells immediate operation was surely indicated. Every case under eighty per cent. could probably have waited, as all but two were encapsulated abscesses or simple inflamed appendices: the two exceptions were cases of gangrenous appendix, both of which had 78 per cent. polynuclears. The relative disproportion of the polynuclear percentage to the total number of leucocytes did not seem of much value, as six out of fourteen cases of diffuse or spreading appendicitis showed no disproportion. Noehren cites a few cases in which the history and physical examination left one in doubt as to whether an immediate operation was necessary or not; the polynuclear percentage was high and the condition found subsequently warranted immediate operation. We may thus conclude from his studies that the differential leucocyte count is of value in deciding whether an appendicitis case should be operated upon immediately or whether it can wait. None of his cases with a polynuclear percentage of over eighty could have been considered a waiting case. Noehren does not mention how many cells were counted in each case, stating only that the differential count is a simple procedure which can be more quickly accomplished than an ordinary leucocyte count. This is hardly correct, when we consider that five hundred cells should be counted to obtain an accurate idea as to the percentage of polynuclear cells.

Differentiation of Pathogenic from Nonpathogenic Streptococci.

In 1897 Bordet observed a peculiar color of the blood of certain animals that had died of an acute streptococcus infection, which he interpreted as evidence of hemolysis. A few years later Schottmüller claimed to be able to differentiate pathogenic from nonpathogenic streptococci by this means. He held that after inoculating solid blood-agar media with pathogenic streptococci a clear zone (hemolysis) would be found around each colony, while a green zone would result if the organism was nonpathogenic. His findings being based on nine years' experience are deserving of consideration, yet they have by no means been generally accepted. In the *Zeitschrift für Geburtshilfe und Gynäkologie*, Vol. 61, No. 3, F. Freymuth describes his experiments regarding this subject, the merits of which do not confirm Schottmüller's conclusions. He used twenty-six varieties of nonpathogenic streptococci obtained from pregnant women just before delivery, women who later had a normal puerperium. The pathogenic variety was obtained from the uterus of a woman who died of puerperal sepsis. Eight different kinds of blood-agar media were inoculated with the different streptococci. He found that the kind of medium and the amount of blood used (defibrinated or washed erythrocytes) had no effect on the hemolytic qualities of the streptococci. In all the media all the streptococci at times caused

a hemolysis, and at times none. Occasionally both phenomena were present on the same plate. Both the pathogenic and nonpathogenic organisms when transplanted from a plate on which they caused hemolysis often failed to do so when transplanted to a second plate of a similar medium. Likewise colonies which caused no hemolysis on the first plate caused it when transplanted to a second plate. Freymuth's work is exhaustive, and he reached his conclusions only after making many control tests. We thus see that hemolysis is an unreliable indication of the pathogenicity of streptococci.

Lung Suture in Penetrating Wounds.

Most instruments which penetrate the parietal pleura touch the visceral pleura and invade the parenchyma of the lung for a greater or lesser distance. Besides dyspnea, hemorrhage is very frequently an alarming symptom of such accidents. If large vessels are injured or the hemorrhage is profuse most surgeons believe in suturing the lung tissue. When hemorrhage is not alarming all are agreed that closure of the wound is the best way of favoring repair, though they are not agreed as to the best method of closing it. The majority favor packing and careful bandaging. F. L. Dumont, writing in the *Deutsche Zeitschrift für Chirurgie*, Vol. 92, Nos. 4, 5, and 6, recommends resection of the rib, enlarging of the pleural wound, and removal of all blood clots. The wound in the lung, including the visceral pleura, is then sutured; this stops all bleeding and prevents further escape of air through the wound. If the parietal pleura can be brought together he closes it, otherwise he brings the injured lobe of the lung into the pleural wound and sutures it to the edges of the parietal pleura. Then he closes the muscle and fascia wounds. The advantages he claims for this method are that he is sure to stop all hemorrhage, thus avoiding a hemothorax which might cause serious disturbances by displacing the mediastinum. Even if the hemothorax is absent the pneumothorax alone often pushes over the mediastinum, thus affecting injuriously the heart and healthy lung. This pneumothorax is done away with by suturing the parietal pleura or fixing the lung in the wound, Dumont preferring the former if possible. These are advantages, to be sure, but his other claim that absolute closure by suture makes an infection less likely is contrary to the belief of most surgeons, and only further successful experience with his method will prove that this claim is true. He believes that even if an empyema sets in secondarily the curing of the hemopneumothorax puts the patient in such good condition that he can readily stand a thoracotomy for empyema.

Diuresis Following Ether Anesthesia.

It is usually thought that ether anesthesia leads to a more or less pronounced retention of urine. P. B. Hawk (*Journal of Medical Research*, May, 1908) has tested the correctness of this view by a series of careful experiments upon dogs, in all of which preliminary nitrogen equilibrium was secured. In every instance the ether narcosis was followed by an initial diuresis, which usually persisted for some time; the urine first voided after the anesthesia possessed higher specific gravity than under normal conditions, and in seven out of nine cases was changed from the normal acid to amphoteric in reaction. Of further interest was the observation that the animals suffered an invariable loss of flesh.

News of the Week.

Healthy Year for New York.—For the half year ending June 30, according to figures compiled by the Department of Health, there were 38,722 deaths, a rate of 17.46 a thousand. The average deaths for the first six months during the last ten years was 48,386. Measles and scarlet fever show an increase in the number of cases; diphtheria and croup are about stationary, as are also the deaths of children under five years of age; but typhoid fever, tuberculosis, pneumonia, and cerebrospinal meningitis show substantial decreases.

The Fourth's Toll.—Early statistics collected by the *Chicago Tribune* showed that the Fourth of July celebration this year cost the lives of forty-eight persons, while the injured numbered 1,124. The death list of New York City up to midnight, July 4, was seven, and the number of known injured over 300.

The Floating Hospital of St. John's Guild began its summer trips on July 6. The hospital has accommodations for 1,600 people. Six trips a week are made, two from the east side and two from the west side of New York, and two from Brooklyn. A physician and seven graduate nurses are in attendance.

Roof Pavilion for the Roosevelt Hospital.—Plans have been filed for remodeling the south addition of the administration wing of the Roosevent Hospital so as to provide for a roof pavilion for the fresh-air treatment of surgical cases. A space thirty-nine feet long and twenty-nine feet wide will be available. The additional interior space gained by changing the peak roof into a flat one will be used for hospital purposes.

Charitable Bequests.—By the will of the late William Barr of West Orange, N. J., a number of institutions in Orange and in St. Louis, Mo., receive bequests. The Orange Memorial Hospital and the Record Ambulance Maintenance Fund of Orange each receive $5,000. St. Luke's Hospital, the Children's Hospital, and the Episcopal Orphans' Home, of St. Louis, each receive $10,000, and St. Mary's Infirmary, Bethesda Home, and the Blind Girls' Home, of the same city, receive each $5,000. Almost the entire estate of the late Benjamin Rose, of Cleveland, Ohio, has been left for the founding of institutions for the aged and for deformed children. The estate is thought to amount to almost $5,000,000. St. Francis Hospital and St. Joseph's Home for Consumptives, New York, each receive $2,000 by the will of the late Thomas Cunningham. By the will of the late William Farr of Philadelphia the sum of $7,000 is bequeathed to the Medical, Surgical, and Maternity Hospitals of the Women's Homeopathic Association, and $5,000 to the Jewish Hospital Association.

To Drive Out House Flies.—The Water Pollution Committee of the Merchants' Association of New York, has asked the Board of Health to undertake the distribution among householders and hotel and restaurant keepers, of cards bearing rules of value during "fly time." Some of the rules are as follows: "Keep the flies away from the sick, especially those ill with contagious diseases. Kill every fly that strays into the sick room. His body is covered with diseased germs. Do not allow decaying materials of any sort to accumulate on or near your premises. All refuse which tends in any way to fermentation, such as bedding, straw, paper waste, and vegetable matter, should be disposed of or covered with lime or kerosene oil. Screen all food."

Free Ferry Rides for School Children.—The children of the public schools in the lower part of Manhattan are to be given free transportation over the municipal ferry to Staten Island, in order to enable them to use the athletic fields there. This is in accordance with a recent resolution of the Sinking Fund Commission.

The International Esperanto Congress meets at Dresden, Germany, in August. An invitation is to be extended to the delegates to hold their meeting in 1909 in this country.

Immigration Statistics.—During the first half of 1908, 377,664 of the laboring element of the United States left the country for Europe. In the same period only 186,586 arrived here. For the same period in 1907, the figures were 155,792 departures and 739,748 arrivals of alien steerage passengers. It is estimated that unless a decided increase soon occurs the figures for this entire year will be under 400,000 arrivals. In order to disprove statements made by the Immigration Restriction League that steerage conditions should be radically changed and the companies compelled to provide 25 per cent. more cubic space, a representative of the National Liberal Immigration League with his family sailed recently in the steerage of one of the French Line steamships.

Draining Mosquito Marshes.—The contract for the draining of the Cheesequake Meadows, N. J., the breeding place for New Brunswick mosquitos, was awarded last week. The work is under the direction of Prof. John B. Smith, the State entomologist, and is being extended systematically down the coast. This year territory as far south as Toms River will receive attention, and next year the lines will, it is hoped, reach to Atlantic City.

The Phi Delta Medical Fraternity held its annual convention in Brooklyn last week. At the dinner on July 3, addresses were made by several of the professors of the Long Island College Hospital.

Dr. Osler and the Homeopaths.—A letter written by Dr. William Osler in response to an invitation to speak at the annual dinner of the Alumni of the New York Homeopathic College in May, 1905, has recently been made public. It is as follows: "Dear Dr. McDowell—I do not think that we have a common ground at present so long as your school clings to the law of similia, which from the modern scientific point of view is as antiquated and unreasonable as is the so-called allopathic system from which we modern physicians have departed. With kind regards and best wishes, and thanking you most sincerely for the compliment, sincerely yours—William Osler." This was the basis for the assertion made this year and widely quoted in the newspapers, that Dr. Osler had called the homeopaths a "bunch of quacks," an imputation which Dr. Osler resented and which has called forth his denial and the copy of the letter as above. Dr. Osler says, in writing to the New York *Sun*: "I do not often take the trouble to correct newspaper statements, but I could not allow such a barefaced lie to be circulated without a denial."

Pure Water and Typhoid Reduction.—The total number of cases of typhoid fever in Philadelphia for the six months ended June 30 was 2,195, and the number of deaths from the same cause 351, as compared with 4,995 cases and 606 deaths for the corresponding six months of the preceding year. This most gratifying result is attributed almost exclusively to extension of the system of filtered water, which it is believed will be complete by April, 1909.

Dr. S. A. Knopf of this city has been appointed honorary president of the Congress of French Speaking Physicians of North America, which is to be held in Quebec on July 20-22. Dr. Knopf will deliver an address entitled "Le Sanatorium, le Dispensaire et l'Hôpital Spécial pour le Traitement des Tuberculeux."

To Stop Adulteration.—Farmers and dairy owners who transgress the regulations of the Chicago Health Department will have to contend hereafter not only with the city but with the State of Illinois. Negotiations have been practically completed between the milk inspection bureau of the Chicago Department of Health and the Illinois State Board of Health, through which the two bodies will cooperate in inspection, giving each other the benefit of all information gathered and assisting each other in prosecuting persistent offenders. As an immediate precaution against the sale of watered or tainted milk in Chicago, the City Inspectors will begin taking samples of milk from all cans shipped into the city. The shipments of six thousand dairies and farmers will be inspected and tested for any traces of watered milk. All dairies supplying Chicago will be graded on a basis of 100 per cent. Those which are marked 60 per cent. or lower will be notified to clean up immediately, and copies of the notifications will be sent to the State Board of Health. It is hoped that great results will be achieved from this plan, thus increasing efficiency and preventing disease.

Medical Inspection of Schools in Chicago.—The medical inspectors of Chicago public schools examined 5,819 school children during the week, and excluded 179 on account of contagious diseases. Physical examinations of school children to the number of 3,763 have been made since June 20, 1908. Of this number, 2,389, or 63.5 per cent., were found to need medical or surgical attention.

Civil Service Examinations.—On July 25, 1908, the State Civil Service Commission will hold examinations for the positions of State Prison physician, at a salary of $2,000, and of Woman physician, State Hospitals and Institutions, at a salary of $1,000 to $1,500, and maintenance. Information and application blanks will be sent upon request to the Chief Examiner of the Commission at Albany. The last day for filing applications is July 18.

American Hospital Association.—The tenth annual conference of the American Hospital Association will be held at Toronto, Canada, on September 22 to 25, 1908.

Plague in Caracas.—The German minister to Venezuela in asking for official information regarding bubonic plague in Caracas, has called forth the first recognition by the government of the existence of the disease in the city. The closing of an infected market and other stores has resulted, and the building of a hospital is planned. La Guayra reports no new cases. At Porto Cabello, Venezuela, a fever, thought to be yellow fever, but probably the plague, is said to be epidemic. The situation in Trinidad is improving.

Rats to Go.—Preparations for a wholesale extermination of rats have been begun in New Orleans by the Board of Health. A number of the rodents are to be inoculated with the virus of a fatal disease and turned loose so that they may infect other rats. If first experiments prove successful, thousands of rats will be inoculated and sent out all over the city.

Posters in Tuberculosis Campaign.—The Committee on the Prevention of Tuberculosis has sent out copies of a poster which they have had prepared to 10,000 Italian families in New York. The poster is a brightly colored, lithographed scene in Venice, which it is thought will appeal to the Italians, and on the wide margin good advice as to fresh air, proper food, temperate habits, etc., is set forth. The same idea will later be carried out among other nationalities.

Uniforms for Doctors.—The San Francisco Board of Health at a recent meeting ordered that after July 1 all employees of the Board be required to wear "olive drab" uniforms. A motion that the wearing of the uniform be optional with the doctors in the employ of the Board was voted down.

Marriage Licenses.—During the month of June, 4,476 marriage licenses were issued in New York City. The total number of licenses granted for the first six months of the year is 15,102.

Nurses' Home Opened.—The headquarters of the Royal National Pension Fund for Nurses in London were opened by the King and Queen of England on July 4. The welfare of nurses has been the especial care of the Queen for many years, and the buildings which were built and will be maintained by contribution from many wealthy persons are designed to provide for a cocmfortable old age.

The Iowa Union Medical Society held its semi-annual convention on June 22 at Iowa City. The following officers were elected: *President*, Dr. L. W. Dean, Iowa City; *Vice-President*, Dr. W. R. Whiteis, Iowa City; *Secretary*, Dr. A. Crawford, Mt. Vernon; *Treasurer*, Dr. G. P. Carpenter, Cedar Rapids; *Board of Censors*, Dr. Edwin Burd, Lisbon; Dr. J. W. La Grange, Marion; Dr. H. W. Bender, Cedar Rapids.

The Wisconsin State Medical Society at its meeting on June 26 elected the following officers: *President*, Dr. Gilbert E. Seaman; *First Vice-President*, Dr. H. J. Stalker, Kenosha; *Second Vice-President*, Dr. J. M. Dodd, Ashland; *Third Vice-President*, Dr. H. B. Sears, Beaver Dam; *Secretary*, C. S. Sheldon, Madison; *Treasurer*, S. S. Hall, Ripon.

Obituary Notes.—Dr. John A. Royer of Toledo, Ohio, died at the Toledo Hospital, on June 14, from cerebral hemorrhage, at the age of 67 years. Dr. Royer was a veteran of the Civil War and a graduate of the Bellevue Hospital Medical College in the class of 1867.

Dr. Peter V. Burnett of Brooklyn was killed, on June 29, by a fall from the roof of the Mt. Sinai Hospital where he was a patient. Dr. Burnett was graduated from the New York University Medical College in 1876, and was widely known as a specialist in diseases of the nose and throat. He was 54 years of age.

Dr. Alfred McLaughlin of San Francisco died on June 23, at Pleasanton, Cal., after a long illness, aged 37 years. He was a graduate of the Medical Department of the University of California.

Dr. Daniel W. Lynch of West Bend, Wis., died at his home on June 25, from a complication of diseases. He was 61 years old. Dr. Lynch was graduated from the Northwestern University in 1875, and after post-graduate courses abroad settled in West Bend, where he had since practised.

Dr. Henry Ganter of Floraville, Mo., died suddenly on June 26, of heart trouble, at the age of 59 years.

LETTERS TO A NEUROLOGIST.

To which are appended brief replies purporting to set forth concisely the nature of the ailments therein described, with remarks on their appropriate treatment.

VIII. Hysteria in a Young Man.

Toronto, December 2, 1907.

Dear Doctor:

My wife's cousin is a doctor in New York. Some time ago I wrote to him and described my case, and he advised me to consult you. My occupation, that of buyer for a clothing house, takes me to your city twice a year, and I should like to call upon you the next time I go, if, after reading the description of my sickness that I enclose, you think you can cure me.

I am thirty years old, and have been married for three years. My present complaint is numbness of the tongue, pricking sensation in the left side of the face, bad taste, sense of suffocation, throbbing sensation in the left ear, and occasional headache. These symptoms sometimes come very frequently and last for a few minutes. In addition, I have shooting pains in the left side of the head and occasionally a queer feeling of heat in different parts of my head. These are the symptoms which I have most of the time, but in addition to them I have very queer attacks.

The first attack occurred the 12th of April, 1902. I was at home talking to my mother. I had a sensation as if I were very cold. This lasted a few minutes, then I experienced a twitching in the back of the neck and a throbbing, fluttering sensation in the throat, as if an alarm clock were going off there. Then my tongue began to tremble, or, better said, to stick out and draw back rapidly, and my head to twitch and jerk violently to the left, as if I were having a convulsion. I ran into the next room and lay upon the floor. Soon I felt pain over my heart and went into a faint. I don't know how long it lasted. I did not completely lose consciousness, but I recall that I was very nervous and shaky for some time after it.

A week later I had another attack. Altogether, I have had three of these attacks, the last one a few days ago. I was lying on the couch, when suddenly I called my wife, and said: "See my face, how it is twitching?" She tells me that the face and eye of the left side were turned to the left. My left hand twitched, and my breathing became irregular and spasmodic. This lasted about twenty minutes, during which time I could not see, hear, or articulate. I could only mumble, although I knew perfectly well what I wanted to say. I did not lose consciousness, and I knew what was going on all the time.

So far as I know, the only cause that I can attribute for the first attack was fright. One week before it occurred I went, at the request of a friend, to visit his daughter, who was confined in an asylum in Rochester. As soon as I came into her presence she rushed at me, as I thought, to attack me, but I found out later that she wanted only to kiss me. Soon afterward I experienced a sensation which started from the stomach and went to the throat, and then to the left side of the face and head. When she made the attempt to jump at me, I had a sensation in the lower part of my spine as if it were being forcibly opened, then a queer crawling sensation in my back, and finally I became cold and nauseated. I could not get out of there fast enough,

and when I got home I took some whiskey, but I could not sleep, not only that night, but for several nights. I thought she was always back of me. I had diarrhea and was all excited. I remember now that I had an attack once before something like this one. I had gone to visit my father, who was working in Rochester. I was talking to him, when suddenly I felt a sensation in the throat as if I were choking, and I was seized with the fear that I was going to die. I ran into the yard, and someone gave me whiskey, which I drank, and felt relieved. I remember now that I had a terrible sensation of pressure on my chest.

I forgot to say that in July I had an experience which may have had something to do with bringing on my first attack. I had gone off with a party on an excursion, and we were sitting down to have some refreshments. Someone said to me, "What will you have?" and I said, "I'll have some raspberries." One of the girls said, "Your face looks as red as a raspberry." I immediately became chilly, and had these peculiar sensations in the throat, the significance of which at that time I did not know, but I have had them so often since that I have become accustomed to them. After that I felt very queer and weak.

An attack comes on about as follows: I feel as if something starts to draw in my throat, then comes a sensation as if I were going to vomit or belch gas. Then the tongue begins to shake and harden up on one side like a cramp. It continues to work harder until I get frightened and excited, and it keeps on working faster until my face gets flushed like someone ashamed, and makes the blood go to the head. Then I stand up and say to myself, "What is going to come? I only hope it will go over quick." Then my hands begin to go; I can see and hear, but after that I cannot see and hear, and when I get down on the floor I cannot tell whether it is dark or light. It seems that when I look at a certain thing, I see it perhaps for a second, then it passes away and I lie down. I never lose consciousness until I fall into a deep sleep. In the first attack I had a pain in the heart, and lower down—a feeling as if something were going to break or burst.

The most curious thing about these attacks is that they have some relation to dreams. I have had about twelve dreams of them. I dream that I am at my work and that something comes up behind me which frightens me—never two people, always one person or a dog. Then I am aware that this twitching on the side begins, the dog or person still following me. Then I awaken. Sometimes when I go to bed I am in an excited state and I get these suffocation sensations perhaps a dozen or twenty times before I fall asleep. When sleep comes I begin to dream, and in these dreams it seems that I am walking on the street or I am in a street car and consumed with fear. I am always in fear, and as I walk further I meet a person or a dog and they frighten me, and during this fright I begin to get cold just the same as I do in the attacks. I get very excited, my face begins to twitch to one side, my head goes over, and I lay down on the flfloor or on the ground, and my hand begins to work up and down, also my head. Then I am awake, but soon I fall into a deep sleep. Also about my tongue—I have dreamt several times that I am losing my tongue, and sometimes I think food, or something I had in my hands, gets between my teeth. There is no pain, but it seems very funny, very peculiar, and I can't describe it so well. It seems as if a mouthful of meat has got between the teeth, and I take hold of it and pull it out, and the more I pull the more I get, and then I awaken all excited, nervous, and irritable. I feel sometimes that the hair of my head stands right up straight, and I have a numbness of the scalp—like a creeping sensation on the scalp. I have also dreamt that I have been in the same house where I had my first attack. I sometimes dream of people who are in that house, and it makes me feel very bad, and I begin to get this peculiar feeling which starts from the solar plexus, or the stomach, and gradually goes up to the throat like a ball—but sometimes I overcome it, I do not always go into a convulsion. Then I dream that I have a convulsion when people are talking to me on this subject, and when I awaken there is nobody around me—I am in bed all the time. I also dream at times that I am suffocating. I sometimes suffocate so that I think I am going around like a wheel for about three or four seconds. This is about all I can say of the dreams. But the tongue—I have often dreamt, then I was pulling something off my tongue like flesh—often.

The only thing about my family history that I know is that my father, when he was twenty-two years old, had a convulsion of some sort. He was sitting on a chair and fell off, and does not know anything that happened just before or for some time after. I have one sister, who, when eighteen years of age, was sent to a sanatorium for a period of two months—she was like in a mild attack of mania. She has since been well and working. They say that when I was a child I used to have fainting spells whenever anyone looked at me. For instance, my mother says that, when I was going to school, if anyone looked at me on the street I would faint, then they would put something over my face, and I will be all right again. That was in Europe, and I don't remember anything about it.

For a week preceding the last attack I was said to be very irritable and discontented, nothing seemed to please or satisfy me. After an attack, I feel nervous, frightened, and agitated. I have seen a great many good physicians, among them, Drs. ....., ..., ..., ..., ..., ... and nearly everyone else whom I have been told might help me. Will you please let me know what you think is the trouble with me and what chance have I to get better. I shall do my best to follow out any treatment you may prescribe.

New York, December 6, 1907.

Dear Sir:

I have read the account of your illness that you sent me a few days ago, and I am able to answer your questions. You are suffering from hysteria, and your chances of recovery depend upon what you mean by recovery. If you mean, will you be able to rid yourself of the attacks that you describe, I think I can say to you that you will succeed. If you mean, can you divorce yourself entirely from the nervous instability of which your symptoms are manifestations, then I think the question cannot be answered in the affirmative.

I know of no more difficult task for the physician to set himself than to attempt to say to a lay person of average intelligence and education, what is meant by hysteria. There is less agreement among physicians as to what hysteria means than about any other subject. By some it is used to indicate emotional instability and the possession of symptoms which are feigned, both of which could be overcome by the patient if he or she exerted their will power. This view is not taken by the laity alone—it is even held by some physicians. On the other hand, hys-

teria is used by some as a term of opprobrium, and a person is said to have hysterics in the same way as they are said to be an anarchist or a free silverite, or a Mormon.

In former days, "hysteria" was thought to occur only in females, and it was supposed to flow in some mysterious way from disorder of the reproductive organs; but such ideas have long since given way to the conception that it is a disorder occurring in persons who have inherited an unstable nervous organization, and who, particularly, are "suggestible," who have been exposed to some emotional or mental shock, such as fright. In other words, the word "hysteria" is being used to denote disorder of personality. We know its manifestations just as we know the manifestations of personality, but the constitution of personality is difficult to define.

We may be very familiar with a thing, still be unable to define it—electricity, for instance. We know its properties, its manifestations, capacities, at least in part, but just what it is we do not know. We are in much the same position about hysteria. There are few diseases that have been more thoroughly studied, and not many whose features are more readily recognized. An eminent French physician, Lasegue, said many years ago that a definition of hysteria had never been given, and never will be Despite the fact that many have tried to define it, and some have maintained success in this direction, the statement of Lasegue still remains true.

The most generally accepted view of hysteria today is that it is a special mental state—call it disease if you like—due to cerebral insufficiency. This cerebral inadequacy makes itself manifest in so many ways that the resulting symptoms are almost innumerable, and they may parallel those of any disease. We have been in the habit of stating that such symptoms may be classified into those that exist more or less constantly, perhaps without the patient's knowledge, unless his attention has been called to them, and which are known as the stigmata of the disease, and those that occur occasionally and which are often transitory. The latter come on abruptly, and apparently are often of much severity, such as in your own case. They are generally described as an "attack." The stigmata are, however, by no means permanent, and they are wanting in the majority of instances.

In your own case, for instance, the symptoms of the "attack" are those which concern you most, and, as your say yourself, they constitute that from which you seek relief. A physician would probably find on an examination of you between the attacks certain symptoms which he would interpret as hall-marks of the disease. What I want to impress upon you is that the disorder from which you suffer exists between the attacks as well as during them, even though the feature of the disease which alarms and concerns you are the attacks, therefore treatment of you must take into consideration your state of health at all times.

It is impossible to outline to you in a letter the treatment you should have in order to relieve you of the distressing and incapacitating symptoms of your disorder, nor do I understand that you request that this be done. The one essential thing for you to do is to place yourself in the care of a physician who is familiar with the disorder hysteria, and who is willing to give as much time as is necessary to determine the cause of your attacks. I believe that he will have very little difficulty in tracing them to fright, for the history you have given of such occurrences in your infancy, as well as the one that occurred when you visited your friend in the asylum, are obviously in causal relationship to your attacks. Appropriate investigation will reveal that there have been other frights which you have perhaps "forgotten," and which are particularly associated with a dog. The memories of these frights must be reawakened and revivified, and when they are brought up to the judicial throne of your consciousness when it is most awake and alert, it must pass upon them, with convincing assurance that they have done you no harm; or, at least, that they have done you no greater harm than that which you have already experienced. It is the lingering memory of these remote experiences that are now out of the circle of the thought-procedure which constitutes your consciousness, or daily mind, as you know it, that is harassing you both in your sleeping and in your waking moments.

Naturally, it is quite impossible for you to do this sort of thing by yourself. In reality, the application of it constitutes what is called psychotherapy. If you are a reader of the daily papers you have undoubtedly often seen this word in print during the past year or two. The art of psychotherapy has been one of the important assets of the physicians since the prehippocratic period; the science of it is now being constructed. To work successfully in the field of psychotherapy one must have a knowledge of psychology, psychiatry, and physiology, unless you happen to be a clergyman of a certain type and are a born psychotherapeutist, not a made one.

I think if you will put yourself in the care of Dr. ..... of your city, a young physician who has had adequate experience in the ..... Hospital here, in the treatment of such disorders as yours, and follow implicitly the instructions that he gives you, relying entirely upon what he says relative to the outcome of your disease, you will soon be free from "attacks."

Yours very sincerely.

OUR LONDON LETTER.

(From Our Special Correspondent)

HOSPITAL SUNDAY FUND—CAMBRIDGE UNIVERSITY—CAVENDISH LABORATORY—IRISH UNIVERSITIES BILL—CORONER TROUTBECK AGAIN—VIVISECTION PARLIAMENTARY RETURN—A SHOCK TO PRUDES—EPIDEMIC OF MUMPS—OBITUARY, A CENTENARIAN.

London, June 20, 1908.

To-morrow is Hospital Sunday, and the usual appeals have been issued. Monday last seems therefore a well-chosen day for the interesting ceremony at the Mansion House. This was the presentation to the Corporation by the Council of the Hospital Sunday Fund of a bust of the late Mr. George Herring, who during his life gave £90,000 to the fund and by his will endowed it to the extent of over £600,000. He was one who disliked being thanked for his beneficent use of the wealth he had attained, but, as remarked by Mr. Holland in presenting the bust, though his life was his own his memory is ours. The Lord Mayor, in accepting and unveiling the bust, said it would be a bright reminder to future generations that such men did not die, and the best appreciation of George Herring's work was to be seen in the letter which the King had sent him some time before his death, a copy of which has been engraved on a plate beneath the bust.

The formal installation of Lord Rayleigh as Chancellor of the University of Cambridge in succession to the late Duke of Devonshire took place on Wednesday. After an appropriate tribute to his predecessor and an expression of thanks for the honor of being elected to the Chancellorship, of which he said "no man, however litle ambitious, could be insensible," he referred to his former associations with the university and humorously alluded to some "connected with certain feverish hours spent in trying to persuade examiners that I knew more than I did." He then passed

on to his "more pleasant office" of conferring the honorary degrees.

On the previous day Lord Rayleigh opened the new wing of the Cavendish Laboratory for Experimental Physics, which has cost between £7,000 and £8,000, exclusive of the amount required for equipment. He spoke of the time he spent as professor there and the help he received from many, including Lord Kelvin, than whom, he said, there was never a more original man. Helmholtz, too, he made the acquaintance of at that time, and he was the only physicist to be put in the same rank as Kelvin. Lord Rayleigh went on to say that since his own retirement the laboratory, in charge of his able successor, Professor Thomson, had increased its fame in every direction, and the young men trained in it, one of them his own son, would be outspoken in recognition of the debt they owe to it and to the direct teaching of Professor Thomson. He then declared the building open.

The Irish Universities Bill is giving Mr. Birrell more trouble than he expected. Apart from the question of the Dublin Medical School, it has aroused antagonisms between the clericals and nationalists. Then on the resumption of the committee stage in Parliament he received a resolution passed by the nonconformist group urging him to agree that affiliated universities shall be absolutely free from denominational tests and atmosphere to both students and teachers. This puts him on the horns of a dilemma. If he satisfies this group he will offend the Roman Catholic bishops; if he arranges with the latter in the matter of Maynooth, the former are likely to desert him.

Coroner Troutbeck is not content with his unenviable notoriety. He still cultivates his dislike of medical evidence unless that of his brother-in-law. He lately held an inquest on a case in which an operation had been performed by Sir Victor Horsley. That gentleman said he did not know why he should have been called as a witness; the case was quite simple and had been duly certified by the usual attendant. The Coroner said that operations had greatly increased and if they were to any extent a cause of death they came within the Coroner's Act. Sir Victor rejoined that if so 10,000 additional inquests would have to be held every year. Sir Victor afterward wrote to the *Times* exposing the absurdity of Mr. Troutbeck's claim, which if allowed would put an end to the practice of surgery, for what surgeon would care to operate if in every fatal case he was called upon to satisfy an incompetent judge of such questions that his operation had not accelerated death? Mr. Troutbeck has written to the *Times* to defend his claim that deaths after operation are not natural, and with the insolence of an incompetent official says: "The objection of Sir Victor Horsley to publicity is significant. Why should it exist?" The Coroner further says that "the people have a right to know the full cause of death in those cases where their relatives have had the misfortune to die after an operation." To any such claim the answer is a direct denial. If admitted it would be just as reasonable to apply it to other than surgical treatment. The people have no right and assuredly no desire to pry into their neighbors' sorrows or intrude on them in their bereavement. The people have no respect for "Coroner's inquest law" and an immense majority have a very great repugnance to inquests in all but the most necessary cases. Moreover, the Coroner's Act restricts their duties to cases in which there is reasonable cause to suspect "a violent or unnatural death," or a sudden death of which the cause is unknown. Mr. Troutbeck will never persuade the people that death after surgical or medical treatment is "unnatural." The holding of unnecessary inquests is also a ratepayers' grievance, as they have to bear the cost. That they would do well to call Mr. Troutbeck to account would appear from a statement in the *Times* that between May, 1903, and February, 1905, he called in his particular specialist, Dr. Freyberger, 816 times instead of the last doctor in attendance. During the same period all the other coroners of London called in an expert in only 46 cases. The correspondence in the *Times* further brings out the fact that on behalf of three medical societies Sir Victor Horsley headed the deputation which in 1903 brought before the Lord Chancellor misdirections of juries by Mr. Troutbeck and consequent wrong verdicts. Lord Chancellor Halsbury said "his impression was not in favor of the Coroner's practice," but he seemed afraid to exercise his only power "to remove a coroner for misconduct in his office." One of the letters in the *Times* says: "Year by year hundreds of death certificates have been registered in Mr. Troutbeck's district in which an operation has been set down among the causes of death. Yet, till he could attack Sir Victor Horsley, who took part in the agitation against him some years ago, Mr. Troutbeck let them pass."

Many other significant statements have appeared in the correspondence in the *Times*, in which a leading article thus summarizes the matter: "Surely it is high time for the Lord Chancellor to intervene. We have now a new Lord Chancellor, who is reputed to have the courage of his convictions. The people to whom Mr. Troutbeck appeals should represent their grievance as ratepayers."

If the mental derangement of the anti-vivi's could be in any way alleviated we might expect much from the parliamentary return issued on Wednesday of the experiments on living animals during the year 1907. It is to be feared, however, that those agitators who pervert the truth will continue to publish the misstatements which have been authoritatively disproved. The comments on the return by the leading newspapers should suffice to relieve the minds of genuine animal lovers, whose sympathies have been preyed upon by unscrupulous agitators. One of the leading papers declares there is no justification for the ideas that were current thirty years ago, and the return shows that the term vivisection as popularly employed is an entire misnomer, and the paper says that the pictures of the dog and vivisector put up at railway stations by anti-vivisection societies are "not only one-sided," but are also "absolutely untrue to life," for "nothing of the sort suggested ever happens." The enormous majority of the experiments in 1907 are shown in this parliamentary paper to have involved no use of the knife at all. Further, any operation capable of causing pain was invariably performed on an unconscious subject. Again, the return says "in no case has a cutting operation more severe than a superficial venesection been allowed to be performed without anesthetics." For the benefit of the "man in the street" I could wish the term superficial venesection had been explained or the less technical one "bleeding" been adopted, for the tradition of bloodletting in disease is pretty well known to all classes. There are agitators who stigmatize the proceedings of the Royal Commission on Tuberculosis, the Sleeping Sickness Committee, or the Cancer Research Fund as vivisection and who do not hesitate to pervert the truth in order to arouse the indignation of their dupes and so extract contributions to their societies. In fact, falsehood seems an important part of the stock in trade of these agitators. When their victims become aware of the nature of the inoculations about which they have heard such denunciations and compare them with the "operation" of vaccination which they have undergone, they will perhaps admit the value of such "experimentation on animals" in the hope of putting an end to some of Nature's extremely painful and prolonged "experimentations" on man, as, for example, cancer, tuberculosis, and other diseases.

"Amazing Statues in the Strand" was the theme of the posters of our sensation papers on Friday and the vigilance association has been called upon to interfere on account of the alleged indecent ornamentation of the new building of the British Medical Association. Of course every doctor has been questioned about it and no little amusement caused. I have not been to look, but those who have tell me there is nothing worse in the statues than is to be seen in most art galleries. Still the staid gentlemen who are supposed to rule the association have been subjected to much annoyance and have put forth the excuse that they had not seen the models—an excuse at which many laugh and others say how diligent they can be on occasion. The *Medical Press* chaffingly offers to introduce the secretary "to an excellent stall in Covent Garden where fig leaves are on sale at popular prices." *The Times* is surprised to find a portion of the London press "assuming the moral attitude of the Pope, who ordered the Vatican Venus to wear tin petticoats." The *Journal* of the Association after a labored defence says it is a case of "an old maid with a spy-glass," and the building committee will leave the statues where they are.

An epidemic of mumps broke out on H.M.S. *Nelson*, the training depot for naval stokers at Portsmouth. Thence it spread to the Royal Naval Barracks. The whole complement of the depot ship was placed under canvas in the recreation ground of the naval hospital and the ship's surgeon and hospital surgeon make an examination every morning for fresh cases. On Tuesday fourteen men and on Wednesday twenty were transferred to the hospital. The vessel is being disinfected and it is intended to keep the company under canvas for a month.

By the death of Dr. Thomas Lambert Hinton, which

took place on Sunday, we lose the senior member of the College of Surgeons, who attained his 100th year on the 1st of May. In 1829 he joined the First Bengal Fusiliers as assistant surgeon, and served with that regiment until 1846. His diplomas were dated 1833. Once on his way home he was wrecked off Cape Finisterre and, before being rescued, swam for some time with a child which had been thrown out to him. He was educated in London, Oxford, and Paris. At one time he held the post of Surgeon to the Reading Dispensary. He had a distinct recollection of the news of the battle of Waterloo.

Dr. Garrett Horder of Cardiff died on the 15th inst., aged 65. He will be greatly missed by earnest fellow workers for the good of the profession, as he was an excellent colleague, and zealous in all good works toward this end. He studied at the London Hospital and qualified in 1866.

OUR PARIS LETTER.

(From Our Special Correspondent.)

SOCIÉTÉ DE CHIRURGIE—GENERAL SPINAL ANESTHESIA—DEATHS OF PROFESSOR TERRIER AND PROFESSOR CORNIL.

PARIS, June 10, 1908.

SPINAL anesthesia was the subject of an interesting discussion at the Société de Chirurgie, M. Chaput defending this method very warmly. In his service, 435 operations were performed after anesthesia by the spinal method was induced, and the mortality of the series was zero. As an anesthetic an isotonic solution of pure stovain was used. In order to prevent the frequently reported headaches following spinal anesthesia the injection of the anesthetic was preceded by the escape of fifteen to thirty cubic centimeters of spinal fluid. The following doses of the anesthetic were used in the work: Four to five centigrams for operations upon the lower extremities and for herniæ; six centigrams for abdominal operations; eight to ten centigrams for operative work on the upper portions of the body. Eight times syncope accompanied with the arrest of the pulse was observed, but the injection of salt solution soon revived the patients. M. Chaput said that the advantages of spinal anesthesia were as follows: Its safety in operations upon the lower parts of the body, the absence of albuminuria and of vomiting following the anesthesia; the possibility of feeding the patients immediately after the operation, except, of course, in cases where abdominal section was necessary. Spinal anesthesia, however, was contraindicated in aged people and in very weak patients, who are specially predisposed to syncope.

M. Hartman warned against the idea that spinal anesthesia is a harmless procedure in all cases, for he had seen two cases of death with this method. During the course of one operation the table was raised and this was followed by the immediate disappearance of the pulse at the wrist, although caffeine was administered hypodermically, and saline solution used by infusion, the patient succumbed after seven hours. The other fatal case occurred under nearly the same circumstances, the operating table being raised in order to elevate the patient's pelvis. Professor Le Dentu thought that, besides the very serious accidents and deaths due to the use of spinal anesthesia, there were many minor effects which would seriously inconvenience the patient. Thus, in a small number of cases, he had observed complete paralysis of the shoulder muscles, which continued for from fifteen days to three weeks. M. Rochard has also observed cases of paralysis following spinal anesthesia with stovain, among them a case of paralysis of an external muscle of the eye, a case of retention of urine, and a case of incontinence of feces.

M. Guinard has observed accidents that appeared some time after the use of spinal anesthesia. In one patient, a woman, paralysis of the lower extremities appeared three months after the anesthesia, the patient dying at the end of one year. The speaker said that he had also observed a case of sudden death which occurred three weeks after the use of spinal anesthesia. In another patient, fifty-two years old, he had noted the appearance of weakness of the lower extremities three months after an operation in which spinal anesthesia was used. The affection seemed incurable, and the malady progressed, ending in the death of the patient within six months. M. Nélaton had likewise observed a case of spinal anesthesia which was followed by incontinence of urine and of feces, the patient finally dying. Several serious consequences of spinal anesthesia had been observed by M. Legueu. One patient, seventy years old, had incontinence of feces and of urine following the operation, and died in six weeks, having lost much flesh and having become quite cachectic during the illness. Incontinence of urine and rectal prolapse appeared in another patient, thirty years old, some three months after spinal anesthesia. This patient, indeed, became ataxic in his gait and suffered from partial anesthesia of the lower extremities. M. Jean Louis Faure thought that spinal anesthesia should be used only when general anesthesia by the usual methods was clearly contraindicated. Personally he preferred chloroform inhalation. Professeur Reclus expressed his unqualified disapproval of spinal anesthesia. He said that in the evolution of animals those survived best who had their spinal cord protected by a cutaneous, a muscular, and a bony covering over and above the cerebrospinal liquid and the triple meningeal membranes. Such protection given to this organ proved to him that the spinal cord was an extremely delicate structure, and it was good policy not to subject it to the influence of toxic substances. He preferred local anesthesia to spinal anesthesia, with the use of the same anesthetic; such method, too, was much less unpleasant to the patient. M. Quenu likewise expressed himself as an opponent of spinal anesthesia and strongly protested against the continuation of the method in further practice.

M. Pièrre Delbet has seen spinal anesthesia used in seventy-nine cases, and his experience has led him to abandon it completely. Among the patients there were two old men suffering from intestinal obstruction, and neither of them survived the operation under spinal anesthesia. In addition he had observed many secondary accidents, such as elevation of temperature, headache, epileptiform attacks, various disturbances of the rectum and of the bladder, usually characterized by incontinence of feces and of urine, and paralytic phenomena in the lower extremities. In his whole series of cases the results had been very unfavorable. As a result of his experience above detailed, he was forced to oppose the method very strongly.

With the death of Professor Terrier there has disappeared one of the greatest and most lovable personages of the French medical community. He was born in the year 1837, and at the age of thirty-five became Adjunct-Professor of Surgery. In 1873, a year later, he received the title of Surgeon to the Hospitals, becoming a little later Professor of Clinical Surgery and member of the Académie de Médecine. He had accepted with great enthusiasm the idea of antisepsis in its first appearance, and it was he who created the aseptic technique of surgery. He was the first to abandon the many useless and even harmful details of the antiseptic technique, and gradually gave the method up completely for asepsis. About this great teacher of surgery there soon gathered a number of disciples, and among them we find the well-known names of Broca, of Gosset, of Robert Proust and others. He was a model of scientific honesty and was always considered as a great figure in the history of contemporaneous medicine. His friends raised their admiration of him to a cult, and even his enemies, of whom he had few, never lacked respect for his personality.

Medical science has suffered another great loss in the death of Professor Cornil, who was always looked upon as a great master of pathology. His scientific work is qute abundant; he commenced by publishing together with Ranvier a manual of pathological histology, which met with a very favorable reception. Later he published studies in nephritis in collaboration with Brault, and they have remained an authoritative exposé of the subject. He also published with Hérard a treatise on pulmonary tuberculosis; in a study of the pathological lesions of syphilis he described very accurately the changes caused by the virus of this disease in the integument. In 1882 he was elected to the Chair of Pathological Anatomy which was left vacant by the death of Charcot. All his scientific works bear the stamp of careful, painstaking, and precise observation; not a detail discovered by his experienced eye was published by him until after it was subjected to careful consideration and control by repeated examinations. The result of this is that his discoveries have become permanent additions to our scientific data. He was an indefatigable worker, standing always on the side of progress and against routine, and ever ready to see and to accept new truths. Every day of over twenty-five years of active work he labored and wrote with the placid peace of a master, and it was this placidity and smiling good fellowship that endeared him to everybody who was brought into relationship with him. In his death the Paris medical faculty has lost one of its greatest ornaments.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

GRAY HAIR—ULTRAMICROSCOPIC EXAMINATION OF MILK—SERUM DIAGNOSIS OF SYPHILIS—ETIOLOGY OF GALLSTONES—DUCTLESS GLANDS AND METABOLISM—A SKIN REACTION WITH DIPHTHERIA TOXIN.

VIENNA, May 15, 1908.

SCHEIN of Budapest has attempted to explain the turning gray of the hair. He says that in older people the hair develops without pigment, and the ordinary course of events is for the pigmented hairs to fall out and be replaced by others without pigment. There is no connection between the turning gray of the hair and the state of nutrition of the scalp. Schein has found in some cases that in areas where the hair previously contained a greater quantity of pigment this disappeared more rapidly than in the hair in the surrounding regions. In cases in which early grayness occurs more pigment has developed in the course of the separate hair generations, and it has also been used up in greater amounts than in other places. When the Roentgen rays are used it is found that at first pigmentation is increased, but later on the hair in the regions exposed develops without any pigment. The deeper the original pigmentation ot the hair, and the more rapidly the separate generations follow each other, the more quickly the hair turns gray, for greater demands have been made on pigment production in the papillæ concerned. It is easy to understand that the exhaustion of the pigment supply is not uniform, for the different hairs are separate individuals with variations in pigment formation and pigment atrophy. Details of the process cannot be ascertained until we have more precise information in regard to the manner in which the pigment is formed in the cells. For the present we must be satisfied with knowing that grayness appears first in those areas in which the hairs have used up the largest amount of pigment, and that pigment atrophy is closely concerned with the question of pigment formation.

Professor Kreidl has examined numerous varieties of milk with the ultramicroscope. In the course of observations on human, cow's, rabbit's, guinea pig's and cat's milk, he found that the first of these differs from all the others in that it does not contain a corpuscular element which is to be observed in the others. In the milk of the lower animals the plasma is densely crowded with a large number of very minute particles which Kreidl calls laktokonia. These possess active molecular motion, and Kreidl is conducting further investigations as to their nature.

Working in Kreibich's clinic in Prag, Klaussner has elaborated a new method of serum diagnosis in syphilis. On diluting small amounts of the serum from papules and chancres with several c.c. of distilled water and adding a definite quantity of syphilitic serum, a flocculär precipitate is formed, while the serum of non-syphilitics either produces no precipitate at all, or the latter appears in very small amount after the lapse of twenty-four hours.

Exner and Heyrovsky have made investigations on the origin of gallstones. They find that the bile acids and their salts are broken down by various bacteria, which, in ascending order of activity, are streptococci, staphylococci, *Bacillus friedländer, Bacillus coli, Bacillus pyocyaneus, Bacillus proteus,* and the typhoid bacillus. The last within five days may reduce the content of bile salts in a medium to one-nineteenth of the original amount. Cholesterin, which forms the major part of gallstones, is soluble in watery solutions of bile salts, and the destruction of the latter renders the cholesterin insoluble so that it is precipitated. The same thing may result through decomposition of bile owing to the action of bacteria. In this way the neutralization of the bile acids results in the precipitation of cholesterin and other substances which form the starting point of gallstones.

Falta, Eppinger, and K. Rüdinger have been studying the relations between the ductless glands and metabolism. Extirpation of the thyroid glands leads to athyroidism and the administration of large amounts of thyroid gland extract causes a condition of hyperthyroidism. It is not possible to induce a similar state of hyperpancreatism or to abrogate entirely the activity of the chromaffine system, but this may be stimulated to hyperfunction through the intravenous injection of adrenalin. The absence of thyroid activity reduces metabolism, the breaking down of albumins being especially affected. In hyperthyroidism metabolism is much accelerated, and it is possible to diminish the demand for albumins by substituting carbohydrates, but in athyroidism this cannot be done. The carbohydrates therefore tend to spare only that part of albumin metabolism which depends on the activity of the thyroid gland. This fact probably has a bearing on carbohydrate metabolism, since glycosuria easily appears in hyperthyroidism. The following experiment illustrates this point: If one milligram of adrenalin per kilogram of body weight is injected subcutaneously into a dog, glycosuria results and albumin metabolism is stimulated. If the thyroid gland is extirpated the glycoscuria does not appear. If the animal is given thyroid extract, however, the injection of adrenalin is followed by a glycosuria. The removal of the pancreas caused adrenalin to become effective on injection into dogs without thyroid glands. The action of adrenalin is therefore influenced both by the pancreas and the thyroid gland.

Schick has reported before the Gesellschaft für Kinderheilkunde the results of experiments made with diphtheria antitoxin in the effort to produce a cutaneous reaction. He found that on making cutaneous inoculations with a concentrated solution of diphtheria toxin, in the course of six or eight hours a papule appears, which at the end of twenty-four hours is surrounded by a red areola, reaches its acme of development on the third or fourth day, and then gradually disappears. The lesion has the same appearance as that produced by v. Pirquet's tuberculin inoculation. The diphtheria reaction is not caused if the toxin has previously been mixed with antitoxin or if the subject has previously been immunized with diphtheria antitoxin. During the first year of life the reaction is usually negative. From the third to the seventh year it is usually positive, only to become negative again after the tenth year. Of twenty-three patients with diphtheria eighteen reacted positively, two reacted very slightly, and in three the test was negative. A positive reaction indicates that the body is deficient in antitoxic substances. The procedure does not have the diagnostic value of v. Pirquet's reaction, but it may be found to be useful in indicating how much serum it is advisable to inject in cases of diphtheria. In the discussion v. Pirquet observed that the reaction possessed a different significance from that with tuberculin. The absence of a reaction showed that there were present in the body active antibodies. Its practical value lay in the fact that by this means it was possible to test out diphtheria antitoxin on human beings. Toxin and antitoxin might be mixed *in vitro* and it could then be determined by inoculation whether the mixture was still toxic or not.

OUR LETTER FROM COPENHAGEN.

(From Our Special Correspondent.)

A MILK EPIDEMIC OF SORE THROAT—TREATMENT OF PULMONARY TUBERCULOSIS BY ARTIFICIAL PNEUMOTHORAX—DEATHS OF DRS. GULDBERG AND BRÜNNICKE.

COPENHAGEN, June 14, 1908.

AT a special meeting of the Medical Society of Christiania an interesting discussion took place on an epidemic of severe angina caused by milk infection. The sanitary inspector of Christiania, Dr. Ustvedt, read the introductory address. On March 3 and following days an extraordinary large number of cultures, sent in by the physicians for examination for diphtheria, were received at the laboratory of the Board of Health. It was at once observed that in the majority of the cases the microbe present was a streptococcus easily to be distinguished by its size, manner of distribution, and predilection for certain culture media. As the same streptococcus kept on occurring in the cultures from new cases, an inquiry was instituted in order to find out, if possible, the source of infection. It turned out that the infection could be traced to the milk of a certain dairy. In many cases whole families were attacked at once, all the members of which had drunk unboiled milk from the dairy in question. In several cases one or more members of a family escaped infection, though the rest of the family suffered from angina. In all these cases it was proved that these persons had not drunk of the suspected milk, while the rest of the family had had the inculpated milk for a beverage. Quite casually it became even possible to trace the infection to a single cow. After several investigations had been carried out without result, one of the veterinary officers of the Christiania inspection of foodstuffs heard that a cow had been slaughtered on a farm which sent its milk to the suspected dairy, and succeeded in finding the frozen udder of the cow in question thrown away among other offal. On examination this udder was found to contain two abscesses in connection with the milk ducts,

from the pus of which a streptococcus was isolated with exactly the same characteristics as those distinguishing the microbe found in the cultures from the throat cases. After this result there could be no doubt that the real source of the infection had been discovered. It was very remarkable that the cow was said not to have presented any symptom of disease, though the pus contained in its udder proved to be very virulent and able to cause a large series of infections in human beings, notwithstanding the fact that it must have been extremely diluted before it came in contact with the mucous membrane of the fauces of the diseased persons. The total number of those notified to the sanitary authorities as suffering from milk angina was between 500 and 600, but many more infections are known to have occurred. The epidemic had its special clinical features, and was, on the whole, of a far more serious nature than the ordinary angina. The onset of the symptoms was very acute, with a rise of the temperature to 104° F. Very pronounced swelling of the lymph glands, not only of the submaxillary but also of the occipital and cervical lateral glands down to the collar bone. A whole series of serious complications of a pyemic nature was observed, albuminuria being very common. Several deaths occurred from septicopyemia. The chief sanitary officer of Christiania, Dr. G. E. Bentzen, read a paper on the introduction of more strict regulations for the milk trade in Christiania, but the measures which he proposed did not meet with general approval from those present. Among the contributions made by the following speakers the most interesting was that of Dr. Malm. He had had occasion to examine the pus both from the abscesses in the udder of the cow and from a suppurating joint in one of the patients who died in the epidemic. The streptococcus found in both cases possesed exactly the same characteristics. He drew attention to the fact that practically all the sufferers in this epidemic had angina, while the ordinary clinical picture in cases of milk infection was that of a gastroenteritis. He had, however, found that Grey-Edwards and Severn had in 1897 observed a similar though far smaller epidemic. According to communications from Stockholm a similar epidemic had also occurred there in April.

At the last meeting of the Copenhagen Society for Physical Therapeutics and Dietetics Professor Saugman read a paper on Forlanini's treatment of pulmonary tuberculosis by artificial production of a pneumothorax. He thought that the method was chiefly indicated in very serious cases, but so far his results had been encouraging. Dr. Würtzen said that he had also tried the method, but his experience was as yet too small to allow of definite statements. His remarks chiefly concerned the technique of the treatment. He has constructed a special trocar together with Dr. Kier-Petersen. It is solid at the distal end and rather blunt, so that it will not easily produce a lesion of the lung. In the middle of the cannula there is a longitudinal narrow slit of two centimeters' length, so that there is every probability that one or other part of this slit will coincide with the pleural cavity. By this means they insure the injection of the nitrogen air into the pleura and not into the lung or other tissues.

The professor in anatomy at the University of Christiania, Dr. Guldberg, has recently died. He was the first representative of the modern teaching of anatomy in his university and has published several important contributions also on anthropological topics.

The Councillor of State, Dr. Brünnicke, has just died in Copenhagen at the age of 85. For twenty-six years he had been physician in charge of one of the departments of the Kommune Hospital and was a highly esteemed teacher.

Progress of Medical Science.

Boston Medical and Surgical Journal, June 25, 1908.

Local Treatment of Acute Inflammations of the Throat from the Standpoint of Pathology.—J. L. Goodale says that in a beginning tonsillitis antiseptic applications may perhaps be used with benefit with a view of aborting the attack, but if this initial procedure does not sterilize the parts, and the usual cryptic deposits appear with systemic involvement, further applications of antiseptics may be not only useless but even harmful. They may diminish the number of bacteria in the crypts which are generating toxin and thus prolong the period required for the formation of the requisite amount of antibodies, and they may exercise destructive action on the tissue cells and phagocytic leucocytes of the host. Antiseptic applications may be followed by increased fever and adenitis, indicating increased absorption of toxin into the system. In certain cases in which acute attacks seem to be aborted by local antiseptics, inflammatory manifestations may shortly follow in neighboring regions and last for a number of days or weeks. Under such circumstances it may be that the checking of the attack checked also the establishment of immunity, and that for its final accomplishment a longer period of growth of the organism upon the membranes of the upper air tract was necessary. Perhaps after all the best plan in case the attack is fairly under way is to put the patient to bed and not meddle with him.

Achondroplasia.—W. N. Bullard and A. W. George summarize as the essential features of this condition the following lesions: Sclerosis of the epiphyseal cartilage while in preparation for multiplication. Lack of serial arrangement of the cartilage cells and deficiency in cartilaginous ossification while processes from the marrow cross the line of ossification. Abundant periosteal ossification produced as well by means of osteoblasts as by direct calcification of the fibrous lamellæ, but only eventuating in the formation of a spongy bone with thick resistant lamellæ. Sclerosis of the bone marrow. They then describe one case which has come under their own observation, and present some excellent radiographs illustrating the difference of the appearance of the bones of the arm and hand as compared with normal conditions. Their patient was first seen when ten months old, and has been under observation for the past four years. It was noted that the patient presented no thyroid gland, and the treatment has consisted in giving thyroid extract in ten-grain doses three times daily—also at intervals cod liver oil and bone marrow. The results have been good, for while the child still presents certain bony deformities his mental development is up to the average and he is able to play as do other children.

New York Medical Journal, June 27, 1908.

The Tuberculin Inunction.—The method of making the tuberculin test without rupture of the continuity of the skin is thus described by E. Moro: A mixture is prepared of Koch's old tuberculin 5 c.c., and anhydrous wool fat 5 grams. Of this a piece the size of a pea is rubbed into the skin of the chest or abdomen, over an area of four square inches for half a minute and then left on the skin to absorb spontaneously. On the second day or even earlier a positive result is indicated when small papules appear over the area of the inunction or in its immediate vicinity; negative when the skin shows no changes of any kind. With the positive reaction one often observes only a few very pale papules. Occasionally the papules are very numerous and red, and only exceptionally the skin in the region of the inunction is very much reddened and itches. The papules usually disappear by the end of a week. No other local and no general symptoms have been noted. The author believes that this method is just as reliable as the conjunctival or the von Pirquet methods. Comparison of the latter method and that by inunction led to the observation of the following differences: (1) In advanced cases of tuberculosis the skin loses earlier its reactionary power to the inunction. (2) In cases showing no clinical signs of tuberculosis the percentage of positive results is much smaller in the inunction method. As opposed to the conjunctival and subcutaneous applications the inunction is entirley harmless. The patients never object to its use.

Mercury and Tuberculosis.—W. F. Bernart says that mercury when given by injection possesses certain actions exclusive of its antisyphilitic ones. This applies especially to the bichloride. This drug when injected in full doses has a decided antithermic action in nearly all cases where the fever is the result of some germ invasion. Besides this, it also exerts what might be termed a sedative influence, that is, it decreases the nervous tension, or, as the patient expresses it, it makes him lazy and indolent. This latter action might be the result of a mild metallic poisoning. In view of this, it is not at all surprising that certain tuberculous patients at first seem to be favorably influenced by this method of treatment. In a series of syphilotuberculous patients treated as above indicated the author noted the following effects: (1) The control of the active syphilis in many of the tuberculous patients seemed for the time to benefit the tuberculosis also. (2) In patients with pulmonary tuberculosis, after the first control of the syphilis and if the treatment was continuously pushed, a few months would show a gradual aggravation of the tuberculosis. (3) The genitourinary tuberculous patients, outside of the benefit to their syphilis, showed no improvement in their tuberculosis. (4) Two patients with tuberculous eye trouble were benefited, one markedly so and the other but moderately so. This is not surprising, as the

intravenous injections of mercuric chloride exert a decided and beneficial influence over infections and ulcerations of the eye. (5) The patients with pulmonary tuberculosis, evidently suffering from the absorption of septic materials, probably due to a secondary germ infection, were decidedly benefited up to a certain point, after which, if the mercurial treatment was continued, their retrogression was rapid.

Acute Syphilitic Nephritis.—J. Ballagi refers to the scanty references in literature on the causal relation of syphilis to kidney disease and finds an indefinite consensus of opinion on the subject. He says that a patient with chronic nephritis who acquires syphilis is hardly a fit subject for prolonged mercurial treatment but when it is possible to decide with certainty that syphilitic infection occurred before the appearing of any symptoms of nephritis, and that the patient did not take any mercury at all, then we are justified in suspecting the nephritis to be of luetic origin, and we would not make a mistake in introducing a mercurial treatment. When no history is obtainable, chemical analysis of the urine, saliva, blood, etc., may decide the question. Mercury can be detected in the organismus months after it was incorporated, and with so much more certainty when recent mercurial poisoning—that is, mercurial nephritis—is present. He warns against the injection of calomel or gray oil, but has never had any unpleasant effects from the bichloride in five per cent. solution. The author closes his paper with the history of one personal case, that of a man of thirty-five years, who presented himself with the usual symptoms of an acute parenchymatous nephritis and a very definite history of a syphilitic infection some two months previously. Under bichloride injections the case cleared up satisfactorily. A brief bibliography is appended.

Results Obtained from Use of Diphtheria Antitoxin Refined and Concentrated by Gibson's Method.—The method of Gibson referred to consists in the elimination from the serum of the nonantitoxic substances and is described in the *Journal of Biological Chemistry*, Vol. I, Nos. 1 and 2, January, 1906. R. E. Wodehouse describes his results with this refined and concentrated preparation in a series of 345 patients treated in Toronto institutions. Only four developed an urticaria larger than 10 cm. in diameter surrounding the point of injection. In two the affected area remained confined to the thigh and buttock. In one the abdomen and extremities were involved. In several cases painful myalgia developed. The author's reasons for continuing to use the Gibson preparation are thus stated: (1) In therapeutic use, often 10,000 to 15,000 units of antitoxin are indicated for one injection. If concentrated to a potency of 1,500 units to 1 c.c., 10 c.c. only are necessary for the latter dose, whereas in using the old form of antitoxin, with a potency of 500 units to 1 c.c., the tissues are necessarily distended three times as much by the injection of 30 c.c. (2) The much smaller sized syringe and needle necessary were very potent factors in dealing with neurasthenic, frightened patients, who always see every detail. (3) The systemic affections were markedly reduced. (4) In a hospital where both diphtheria and scarlet fever are treated, the early recognition and isolation of scarlet fever or measles, developing in the diphtheria ward, is most important. When refined and concentrated antitoxin has been used, there is no necessity for retaining patients with erythematous rashes under observation for several days, as we know these rashes rarely follow its use, whereas under the old methods, using the unrefined horse serum, with its accompanying rashes, the early diagnosis was always doubtful.

Journal of the American Medical Association, June 27, 1908.

Hyperemia.—J. F. Binnie describes the Klapp modification of the Bier hyperemia treatment and gives a brief statement of his experience in its use. It consists in the daily application of cupping glasses adapted to the part five minutes at a time, alternating with three minutes' rest, for a total period of forty-five minutes. Suction is produced by means of a rubber bulb or a syringe, and should be strong enough to cause redness; if the part becomes blue or pain or paresthesia is caused, the suction is too strong. The suction causes inflow of blood and increased exudation, thus bringing a more active protective material to the point where it will do the most good. The periods of rest allow the blood to escape and a fresh supply of protective material to be brought. Wright believes that the escaping blood contains a vaccine which stimulates the production of antibodies throughout the system. If pus is present, it should be evacuated by a small cut or puncture and the cupping will aid in its removal. In his dispensary practice Binnie has learned to trust this treatment in those forms of cervical adenitis common among the poor, and usually produces a cure in seven to ten days with notable absence of scar. He has seen a large number of buboes promptly disappear after evacuation under this treatment, and it acts like a charm in the treatment of furuncles, the abortion of boils being frequently produced.

Local Applications in Surgery.—J. E. Moore criticises the belief in the utility of local applications in surgical conditions, the supposed good results following their use being in his opinion attributable to Nature and not to the local remedy. He asks why should we apply morphine locally when it relieves pain only after it is absorbed, and it is absorbed much more quickly when administered by the stomach or hypodermically? It is because we do not give Nature due credit for her healing powers that such an absurd cult as Eddyism has taken such a hold on the public mind. Liniments have their uses, but their curative effect is not demonstrated. They may relieve pain and the massage do good, but Moore considers their greatest effect to be a mental one. It is rare that blisters do more than add to the discomfort of the patient, and dusting powders are deservedly going out of use. Medicated dressings, he asserts, have practically gone out of date, iodoform gauze is about the only one left, and it is on its last legs. Simple protective sterile dressings are all that is needed. Irrigation with strong chemical solutions are still used to an unwarranted extent; anything beyond irrigation with salt solution to mechanically remove retained discharges is meddling. The use of 95 per cent. carbolic acid as recommended by Powell is an important advance, as it destroys all bacteria and may cut short a virulent infection, and if followed within two minutes with alcohol, there is no chance of absorption. Heat and cold are popular and therefore over-used applications. They relieve pain, but their curative value is doubtful. Their use in a deep-seated disease like appendicitis seems to Moore the height of folly. The worst thing about them is that their use may lead to fatal delay. The abuses of hot and cold applications are too numerous to mention, but one of the most frequent is in phlegmon of the hand. Every surgeon, he says, has seen cases in which poultices have been employed until the tendons have been destroyed. The local use of heat in such cases is grateful to the patient, and it should be used for that purpose only, not to supplant or interfere with rational surgical measures.

Colles' Fracture.—Colles' fracture is defined by L. W. Ely as a fracture, usually with impaction, of the lower inch of the radius, almost invariably due to a fall on the heel of the extended hand. The radius breaks here at its weakest point, where the cancellous structure of the bone is not arranged to withstand a force applied longitudinally, and the thicker layer of dense bone just above resists the strain and is driven down into the lower fragment. The outer part of the bone suffers more than the inner because the inner is held fast by the ulna and hence it swings up and receives more of the force of the blow. Not until the styloid process of the ulna is broken and the triangular fibrocartilage is dislocated is the internal portion of the bone exposed to impaction. The fall is also usually on the radial side of the hand. The posterior or dorsal aspect of the bone usually suffers most, and this fact is thus explained by Ely: A section at the usual seat of fracture shows the bone here shaped roughly as a right-angled triangle with the hypothenuse forward. When a force is exerted on a line parallel to the hypothenuse, midway between it and the apex, the apex will yield much more readily than the broad base. Such a force the transverse line of the carpus exerts. Again the bone in the anterior part is much denser than that in the posterior. Pain and disability were marked in a recent case; pressure on the lower three-fourths of an inch of the radius causes pain, and the finger feels a break in the contour. In case of simple slight impaction there will be nothing characteristic beyond swelling and thickening of the radius. Fracture of the carpus, most frequently of the scaphoid, is often mistaken for Colles' fracture. The main diagnostic point here is the extreme sensitiveness over the broken bone, usually in the region of the anatomic snuff-box. The disability is not so great unless there is also semilunar dislocation. If the *x*-ray is used it is well to test both wrists, and sometimes an old fracture of the scaphoid can not be differentiated from a Colles' fracture. The prognosis without treatment is not usually good. The main indication is to break up the impaction and keep the fragments in place. The notion that an impaction should be let alone can not be too strongly condemned. Ely insists on its reduction under anesthesia, not by traction, but by working the fragments backward and forward on each other until crepitation is felt. For a splint, he prefers the plaster-of-Paris gauntlet to any other form of dressing, and gives full directions for putting it on. He applies it from the elbow to the fingers, leaving a wide hole for the thumb, and slits it up on the radial side to guard against damage from swelling. He leaves it on for from nine days to a

month, and insists that, with proper adjustment, immobilization never causes ankylosis.

The Lancet, June 20, 1908.

Sarcoma of the Right Os Innominatum Simulating Appendix Abscess.—The patient of E. H. Harries was a girl of 12 years sent to hospital with the diagnosis of appendicitis. Four days previously she had been seized with a pain in the right side of the abdomen, running down the leg, which was kept bent, constipation but no vomiting. It was learned later that she had limped a little for some weeks. There was a swelling in the right iliac fossa, tender on palpation, and not definitely fluctuating. Immediate laparotomy was decided on and incision made over the swelling, the peritoneal cavity not being opened. Exploration through the wound down into the pelvis gave exit to considerable gelatinous material and necrosis of the ilium was found. The child did badly, and in a few weeks a second operation was done and much foul smelling tissue removed through the reopened original wound. The child still did badly and died in about two months after admission to hospital. Autopsy showed among other lesions the following: In the paravertebral hollow on the right side over the vertebral extremity of the sixth and seventh ribs was an oval soft tumor of about the size of a walnut. On cutting into it soft grayish diffluent material escaped and the seventh rib underlying was found to be eroded. The metastatic spleen nodules were found histologically to present the same characters as the primary bone tumor. The intestines, pancreas, and kidneys showed no pathological change. The mesenteric glands were not enlarged. The right iliac fossa was found to be invaded by an irregular infiltrating diffluent growth. The muscles and fatty tissue in the neighborhood were all involved. On cutting into them purulent grumous material escaped in large quantities. Douglas's pouch was filled with material like laudable pus. The ilium at the base of the growth was found to be greatly eroded. The right psoas iliacus was completely atrophied. The hip-joint was not implicated.

Acidity of the Urine.—Seven cases are reported by F. A. Watkins, who refers to the success claimed by French physicians in treating cases of acid intoxication by the administration of phosphorus preparations which are selected according to the degree of acidity of the urine. The estimation of the acidity of the urine is for the purposes of this therapy carried out by Boussingault's method of titration with a standardized solution of sucrate of calcium. Full details as to chemistry, etc., are given in the author's paper. It is important that patients suffering from loss of phosphates should partake of a rich diet in these salts. The following articles are enumerated in the order of preponderating percentages: gruyère cheese, haricot beans, mutton, beef, white cheese, eggs, cereals, and milk. Cerebos salt contains 4 per cent. of phosphates, so is an important adjunct to the diet from the point of view under consideration. With regard to drugs, phosphoric acid and its salts, according to the degree of acidity of the urine, are all useful. If the reaction is normal, the phosphorus should be given in neutral form. For this purpose a new salt called sodium sesqui-phosphate has been introduced. Two grams per day are given in divided doses. The author claims that the best remedy for raising the urinary acidity is phosphoric acid but it must be given in large doses. If the specific gravity is much above normal much water should be taken with the design of keeping the urine below 1.020. For this purpose it may be necessary to supply the patient with a urinometer. The alkaline mineral waters are very effective in reducing the acidity of the urine; but during their exhibition it is very necessary to make periodic estimations of the urine so as to regulate the dose of alkalies. If the hyperacidity is only moderate it will rapidly yield to effervescing phosphate of sodium. In greater degrees of acidity it may be necessary to give the alkaline phosphate of sodium. It is a much easier matter to lower the acidity than to raise it.

The Supports-in-Chief of the Female Pelvic Viscera.—R. H. Paramore regards the mechanical side of this question as still unsettled. Mere study from the side of anatomy is insufficient, for we must at the same time bear in mind actual living processes. He describes the pelvic diaphragm in great detail and calls attention to the analogy between the collective supports of the uterus and those of the duodenum. He says that when we glance at the visceral connective tissue strands which radiate from the circumference of the pelvic wall to the cervix it, indeed, looks as though these strands might support the uterus. But when we compare this apparatus with the pelvic diaphragm lying beneath we find the essential difference between these two structures is, that while the pelvic diaphragm on account of its striated muscle, is a highly elastic obturator, the pelvic visceral connective tissue is little if at all elastic. It is this lack of elasticity, the impossibility of yielding to excessive pressure from above without stretching, and the equal impossibility of returning to a previous position after such stretching that makes it impossible for the visceral connective tissues to play the part of a support adaptable to all the requirements of the pelvis. Such connective tissue, however, does prevent the too great descent of the uterus during defecation. The pelvic diaphragm should be considered as identical in structure and function with the anterior abdominal wall. The pelvis and abdomen are essentially one cavity, but since the area of the pelvic outlet is many times smaller than the area filled in by the anterior abdominal wall, the work to be done by the levator ani muscle, in successfully resisting the pressure caused by increase of the contraction of the abdominal wall muscles, is considerably less than the work which the anterior abdominal wall musculature has to perform to produce this pressure. Thus a relative thinness and apparent weakness of the levator ani muscle is explained. The outcome of the simultaneous contraction of these two groups of muscles, in the superior one of which the thoracic diaphragm must, of course, be included, is the intraabdominal pressure. This pressure acts by thrusting the pelvic viscera still further downwards upon the pelvic floor; and in the presence of this downthrust the viscera are maintained in their position by the levator ani muscle. Since this is attached to the pelvic wall by connective tissue it is plain that to this the strain and stress of supporting the viscera and opposing the intraabdominal pressure must be transmitted. An inquiry into the conditions of successful connective tissue functioning in the body shows that this is entirely dependent upon the functioning of the muscles with which the connective tissues are connected.

Berliner klinische Wochenschrift, June 15, 1908.

The Treatment of Ileus.—Braun discusses the question of the indications for surgical treatment in intestinal obstruction and the results of such treatment. The operation is indicated in almost all cases in which the diagnosis of mechanical ileus has been made, and the full symptom picture of the obstruction is not to be awaited in such cases, especially as more or less exact diagnosis as to the nature of the condition and to the localization ought nowadays be made quite early. Braun has observed sixty-nine cases, of which twenty-seven or about 40 per cent. died. Five of the fatal cases, however, resulted from the original disease, carcinoma, and not from the obstruction, which was successfully relieved. Six patients were cured by high irrigations, eleven out of the thirty-three patients in whom the obstruction was a primary condition were cured by the laparatomy, the rest dying in spite of the operation. Palliative measures, among them punctures of the bowel, enterostomies and enteroanastomoses were used in thirty patients suffering from tumors or adhesions. Fifteen of these latter were cured by the treatment.

Ophthalmodiaphanoscope.—Under this name Hertzell describes an instrument constructed by him, which is introduced into the mouth and illuminates the fundus of the eye from the back. The fundus may then be observed directly, the new illuminations offering many advantages over the usual ophthalmoscope, among them, simplicity of technique, absence of disturbing reflexes, larger field of vision, and the fact that better attention can be given to the appearances of the fundus, since the illumination need not be kept in mind any more. Hertzell has succeeded in reflecting the picture of the fundus on a screen, and thinks that this may enable more accurate measurements of the papilla to be made in pathological cases, as well as lead to the introduction of direct photography of the eye fundus. Moreover, the new illumination gives somewhat different pictures of the eye conditions from those seen by the ophthalmoscope and may thus lead to better understanding of the normal and the pathological appearances of the fundus.

Münchener medizinische Wochenschrift, June 16, 1908.

Spontaneous Rupture of the Rectum.—Burkhardt says that only fourteen cases of this accident have been reported in the literature, three having occurred in persons not suffering from any disease of the bowel. The other patients were affected by prolapse of the rectum or had diverticula. The author adds another case occurring in a healthy young man during excessive straining in defecation. An operation, with the formation of artificial anus, showed that the peritoneal cavity was opened and feces escaped into it. The patient recovered, making the first case on record of recovery after the intraperitoneal rupture of the rectum.

Artificial Hyperemia in Animal Experiments.—Frangenheim says that under the action of pure hyperemia are included all the phenomena that are produced in acute suppurative conditions by the congestion and the suction.

The experiments with animals are well fitted for the study of such action. If staphylococci or streptococci are injected into the vein of a rabbit's ear, and artificial hyperemia produced at some distant site of the body, that site becomes the seat of an abscess. Other artificially produced abscesses were never diminished by the application of artificial hyperemia, while in control animals the lesions diminished progressively without any treatment. The treated abscesses contained virulent cocci for weeks during and after the treatment. Microscopical examination showed a great deal of young connective tissue in such lesions. Passive hyperemia by means of a bandage likewise had no salutary effect upon artificially produced lesions, the suppuration of joints and of the medulla of bones being made more active by the application. The author concludes that in animal experiments hyperemia has no bacteriological effect, and all the suppurative affections of the soft part, of the joints, and of the bones behave badly under such treatment.

Deutsche medizinische Wochenschrift, June 11, 1908.

The Treatment of Nasal Conditions in Gynecology.—Koblanck says that in addition to the tubercle of the septum and the anterior part of the inferior turbinate bone which were designated by Fliess as the parts to be treated in gynecological practice, the whole septum and the whole of the inferior turbinate may have to be treated in other cases. Indeed, often enough the condition depends upon the affection of the accessory cavities, and these must also be treated. Two results of treatment are especially noticeable, one serving to arouse uterine pains, the other diminishing pain. The latter is obtained by applying to the nasal mucosa a gauze sponge wet with 20 per cent. solution of cocaine; uterine contractions, on the other hand, are called forth by a more energetic rubbing of the mucosa with a sponge dipped into some preparation of the adrenal gland. Not over five to ten drops of the cocaine solution is to be used. While such treatment seems to affect favorably the pain caused by the uterine contractions the pain due to the pressure of the child upon the soft parts in its advance through the genital canal is not affected. The technique of using the adrenalin for the purpose of increasing the pains is to be carefully followed; no bleeding is to be produced even by the energetic rubbing of the mucosa. Especially valuable is this treatment in the period from the birth of the child to the birth of the placenta, which in such cases is expelled very forcibly. Still wider field for this treatment is found in gynecological practice, the general indication being the existence of any consequences of a morbid sexual life or of abnormal sexual excitement. Hysterical phenomena, anomalies of menstruation, neuralgic pains, catarrhal inflammation of the cervix are some of the special indications. "False appendicitis," abnormal decrease of the sexual instinct as well as increase of it are favorable fields for nasal therapy. In addition, the treatment of certain portions of the nasal mucosa is very useful in controlling many disturbances of the heart's function, especially arrhythmias of nervous origin.

The Distribution of the Paratyphoid Bacilli Outside of the Human Body.—Hübener says that investigation carried on by the Royal Health Department of Germany have shown that the bacillus of swine plague which can in no way be differentiated from the paratyphoid B-bacillus is a normal inhabitant of the gastrointestinal canal of healthy pigs. Hübener has succeeded in isolating a like organism from six out of one hundred samples of sausage examined by him. The use of the food in question had not seemed to have produced any ill effects in human beings. It is probable, therefore, that such bacilli may be excreted by the healthy human being after partaking of such food. Moreover, the finding of such bacilli in the excreta of patients suffering from a symptom-complex resembling paratyphoid infection is not sufficient ground for assuming that an etiological relation exists between the bacilli found and the symptoms, unless specific reactions on the part of the patient's blood toward strains of the bacillus can be demonstrated at the same time. From the standpoint of sanitary medicine the findings are of importance showing that the demonstration of such organisms in the food of persons attacked by suspicious disease after partaking of that food is not enough reason for considering that food as the cause of the disease. Rimpau in a second article dealing with the same subject says that in the course of nine months he has discovered twenty-six individuals who excreted paratyphoid B-bacilli, ten of the persons examined having been sick with typhoid fever, five chronic bacilli carriers, and fifteen apparently healthy. The findings were especially frequent in the urine of these individuals, fifteen of them showing this bacillus in the urine. The occurrence of the bacilli in these persons Rimpau explains just as Hübener by the frequent presence of the bacilli in the foodstuffs. As no standard of virulence for the human beings can be applied to these bacilli, Rimpau thinks that all possible measures are in order to protect the food and drink of communities from any possible infection with such bacilli.

Comparative Values of Test Meals.—Würz has examined thirty patients after the administration of the various test meals, and comes to the following conclusions: Riegel's test meal consisting of one plate of soup, 200 g. meat weighed raw, well roasted, 300 g. mashed potatoes, and one glass water, is best adapted to testing the secreting functions of the stomach and could well be accepted as the standard test. Next in usefulness stands Sahli's soup, prepared of 25 g. flour, 15 g. butter, 250 g. water, and one pinch of salt, the flour being browned and then cooked for five minutes. The test breakfast of Ewald forms the least powerful stimulus to secretion. It consists of 5 g. tea, prepared in one-half liter of water, and one roll; the ease with which it may be prepared and the fact that it can be digested by the most delicate patients is enough to justify its use in the diagnosis.

French and Italian Journals.

Examination for Indoxyluria in Mental Patients.—Georgio Pardo describes urine that contains indoxyl as being markedly alkaline, turbid, with a sediment of phosphates and carbonates, increased in reducing power, containing urobilin, having modifications of pigments, and microorganisms in marked numbers such as to render the urine turbid. From his researches he concludes that in the urine of some patients subject to mental disease during periods of prolonged excitement, psychical and motor, the indoxyl is transformed into indirubin. Indirubinuria follows severe disturbances of digestion, as is shown by the alkaline reaction of the urine, the turbidity, presence of the sediment of carbonates and phosphates, and other phenomena that have been mentioned. These are due to the action of bacteria which have emigrated in large numbers into the urinary passages. The clinical significance of indirubinuria is the occurrence of intestinal putrefaction. It signifies an insufficient defense of the organism against infective agents, and especially an insufficient action of the intestine and liver.—*Rivista Sperimentale di Freniatria*, Vol. XXXIII, Part IV.

Diagnostic Value of Enlarged Spleen in Typhoid Fever.—Silvestri has studied 147 cases of typhoid, among which the tumor of the spleen was found in 130 recognizable by palpation. In seventeen it was not demonstrable at any period of the disease. In these cases there were conditions which masked the swelling such as muscular tension and obesity. In all the cases in which the tumor was demonstrable, the symptoms, recurrences, complications, duration of the disease and post-mortem findings were in inverse proportion to the development of the swelling. The author believes that the swelling of the spleen in typhoid is not only an index of the degree of infection, but also of the defensive reaction of the organism.—*La Riforma Medica*, January 20, 1908.

Lumbar Puncture in Meningeal Forms of Typhoid Fever in the Child, and Its Therapeutic Value.—Ch. Reca and Firmin Carles describe the different forms in which meningeal infection in the course of typhoid is found in children. The examination of the cerebrospinal liquid after removal by lumbar puncture is of value in diagnosis and prognosis. The fluid may be found to contain pus mixed with typhoid and other bacilli. It may be clear and still contain these germs. In these two cases there is a direct infection of the meninges by the bacilli of Eberth. Again there may be removed a clear fluid containing an abnormal number of lymphocytes. Here the toxins of the bacilli are irritating the meninges. Lastly, the fluid may be of normal composition and underhypertension. Here the same condition increases the tension. The value of the procedure consists in the abstraction of toxins and bacilli when they are present by repeated punctures, and the relief of tension and of pressure on the nerve centers.—*Gazette Hebdomadaire des Sciences Médicales*, January 26, 1908.

Puerperal Psoitis.—P. E. Launois describes a rare form of puerperal infection which generally comes on at a period some time after labor. It consists of an abscess in the sheath of the psoas muscle, accompanied by all the symptoms of a general septic condition. The symptoms are characteristic; they are pain and swelling in the iliac region, inability to extend the leg, flexion of the leg on the pelvis without abduction or adduction of the member, and the classical picture of septicemia. Acute infection of the hip and sacroiliac joints, coxalgia, perinephritis, and periuterine inflammations must be excluded in the diagnosis. Opening the abscess brings about relief of the symptoms, but a phlebitis may ensue. The author describes an interesting case of this trouble in which the psoas abscess came three months after labor.—*Journal de Médecine de Paris*, January 20, 1908.

Book Reviews.

Hypnotic Therapeutics in Theory and Practice. With numerous illustrations of treatment by suggestion. By John Duncan Quackenbos, A.M., M.D., author of "Hypnotism in Mental and Moral Culture," "Practical Physics," etc. New York and London: Harper and Brothers, 1908.

In the introductory chapter the author enumerates the diseases, cases of which have been "substantially relieved and many of them radically cured by accredited hypnophysicists." This list runs from migraine and intermittent heart to dementia præcox and incipient insanity, from hysteria and epilepsy to diabetes mellitus. The next chapter makes plain the principle of this treatment; it is founded upon the evocation of the control that the "transliminal self" exercises over the organs and functions of the body. The rest of the book treats of the practical use to which this control may be put in treating various pathological states; neurasthenia, delusions, alcoholism, "pathological diffidence," etc., receive a chapter each. In an appendix to the book the author proclaims his belief in clairvoyance, "*x*-ray vision," and other transliminal faculties, and gives "authentic" cases of such powers.

This brief summary of the contents of the book indicate its character and the valuation that may be put upon it by the medical reader. A quotation may serve further in this direction: "In a number of cases moribund patients have been recalled from death by shouting in the ear at the moment of dissolution, a command to return." As an illustration a patient with pneumonia is named, "beyond the pale of hope from a medical point of view," whom the transliminal therapeutist saves, however, by the following command: "Assume immediate control of your physical functions and get well!" directions which "were immediately accepted and implicitly followed!"

The following, addressed to the hypnotized patient, is a part of the author's treatment for diabetes mellitus: "And if your pancreas be crippled in its production of the natural ferment, which is given off to blood and lymph, and which conditions the normal consumption of sugar in the body or restrains the output of sugar from the liver and tissues, you will see that it forthwith pours into your blood or lymph a sufficient quantity of sugar oxidizing ferments!"

In the hands of laymen, this book may be productive of much real harm by exciting false hopes or causing the postponement of medical treatment until too late; its chief interest to the physician consists in the revelation it makes of how far autosuggestion may carry one in the direction of a belief in the unbelievable.

Maladies des Os. Par P. Mauclaire, Professeur agrégé a la Faculté de Médecine de Paris, Chirurgien de la Maison Municipale de Santé. Avec 161 figures intercalées dans le texte. Paris: J. B. Baillière et Fils, 1908.

Muscles, Aponévroses, Tendons, Tissus Péritendineux, Bourses Séreuses. Par Louis Ombrédanne, Chirurgien des Hôpitaux de Paris. Avec 45 figures intercalées dans le texte. Paris: J. B. Baillière et Fils, 1908.

These two books represent the fifth and the ninth fascicles of the "Nouveau Traité de Chirurgie" edited by A. le Dentu and Pierre Delbet. Dr. Mauclaire considers the diseases of bones under five headings: Infections, Parasitic Diseases, Chemical Intoxications (phosphorus necrosis, mercurialism, etc.), Trophic Osteopathies and Neoplasms. The infections are given most attention, osteomyelitis, tuberculosis, and syphilis being exhaustively presented and well illustrated by pictures of gross and microscopical lesions. Rickets is considered under the trophic disorders and the etiological factors in this disease are given due prominence. Sufficient space is alloted to the rarer forms of disease, such as acromegaly, osteomalacia, and leontiasis. The book is especially strong in the description and illustration of the pathology of bone lesions.

Dr. Ombrédanne's is a smaller volume treating of the diseases of muscles, tendons, bursæ and related structures. The author has sought to correct old errors in the classification of the affections in the light of the latest researches. Thus contusions of muscles are classed with lesions involving the solution of continuity of muscular fibers, "pseudo-hernias" are considered logically among the ruptures of muscles, and the various types of myositis are classed with reference to surgical considerations. Treatment is given especial prominence, seven pages, for instance, being given to the technique of tendon suture.

Both books keep up the high standard of the encyclopedic treatise of which they form a part. But one serious fault found in these as in many other books published on the Continent may be pointed out. They lack an index, and the table of contents is not sufficiently exhaustive to make up for the deficiency.

Mount Sinai Hospital Reports, Vol. V, for 1905 and 1906. Edited for the Medical Board by N. E. Brill, A.M., M.D. New York, 1907.

This volume of the Mount Sinai Hospital reports contains much valuable scientific material. In addition to the reports and statistics of the various divisions of the institution, the book contains a number of excellent articles. Among these may be mentioned the article on tumors of the bladder by Dr. F. S. Mandlebaum, and that on Hypernephroma by Dr. A. A. Berg, and a series of special articles on laboratory methods by Drs. Julius Rudisch, E. P. Bernstein, E. Libman, and others.

Woman. A Treatise on the Normal and Pathological Emotions of Feminine Love. By Bernard S. Talmey, M.D., Gynecologist to the Yorkville Hospital and Dispensary; former Pathologist to the Mothers' and Babies' Hospital, etc., New York. For Physicians and Students of Medicine and Jurisprudence. With twenty-three drawings in the text. Second Enlarged and Improved Edition. New York: Practitioners' Publishing Company, 1908.

The fact that this work has reached a second edition is proof of its popularity and the demand for it. The book is evidently written with the object of supplying in a single volume information of occasional value for the physician which could otherwise be obtained only by a long and tedious search through the literature, and it amply fulfils this purpose. It is questionable, however, whether many of the facts given will be of use even to the physician, and if the book should fall into the hands of lay people, especially of the young, it might do more harm than its strictly professional use would do good.

Rabies: Its Place Among Germ Diseases and Its Origin in the Animal Kingdom. By David Sime, M.D. Cambridge: The University Press, 1903.

Before Pasteur began his investigations into the cause of rabies, it was not known that there was a microbe producing a virus that caused rabies. And for a long time afterwards it was thought that the disease had its origin in the canine species. Dr. Sime gives pretty conclusive proofs, however, that the rabbit and not the dog is the animal in which rabies arises. He classifies animals as the hunting and hunted and also with respect to their behavior toward the rabific virus, whether they intensify or attenuate the disease. The intensifiers are the hunted class, and the attenuators the hunting class. Considerable space is taken up in proving that rabies does affect the rabbit first, and that the central nervous system bears the brunt and is in fact the seat of the disease. The most affected parts are the medulla oblongata and the lumbar enlargement of the spinal cord. The treatment is not considered.

The book is not a text-book, but a treatise based on the wide researches that have been made in regard to rabies, and theories and deductions drawn therefrom. As the author says: "It is a study of rabies in a threefold direction, its causation in the individual organism; its place among germ diseases with the end of bacterial agency in the animal economy; and lastly its origin in the animal kingdom."

Prostatic Enlargement. By Cuthbert S. Wallace, M.B., B.S. (Lond.), F.R.C.S. (Eng.), Surgeon to the East London Hospital for Children, etc. Bacteriology by Leonard S. Dudgeon, M.R.C.P. (Lond.), Bacteriologist to the St. Thomas Hospital, etc. London: (Henry Frowde, Oxford), Hodder and Stoughton (Oxford Medical Publications), 1907.

This monograph contains the results of researches on the pathology, bacteriology, and operative treatment of prostatic enlargement. The volume opens with a consideration of the surgical anatomy of the gland; the physiology of the prostate and the morbid histology of prostatic hypertrophy are next dealt with. Most hypertrophied prostates were found to have distinct fibrous capsules. The nonencapsulated forms were rare. The enlargement was found to be neoplastic in character, and the chronic inflammation found in the affected glands is probably secondary and due to infection. The latter is dealt with in the bacteriological section. The most frequent germ found in hypertrophied prostates was the *Staphylococcus albus*, next the *Bacillus coli*. The urine did not always show the character of the infection in the gland. Freyer is credited with the introduction of the suprapubic operation of prostatectomy. No mention is made of the work of Fuller, Guiteras, and others in this country, save Hugh Young, who is quoted briefly. The enucleation of the prostate from within its capsule is to be regarded as the essential step in "complete" prostatectomy.

Gout, Its Pathology, Forms, Diagnosis and Treatment. By Arthur P. Luff, M.D., B.Sc., F.R.C.P. (London), Physician to St. Mary's Hospital. Third edition New York: William Wood & Company, 1907.

Luff's monograph on gout needs no introduction to the progressive physician. It is said that no nation knows more about gout than the English, and certainly the present volume is one of the most satisfactory treatises on this disease of metabolism that have been offered to the profession within recent years. Beginning in Part I with the theoretical consideration as to the causation of gout, the formation of uric acid, the relation of the blood to gout, and the formation of gouty deposits, the author passes on in the next section to the clinical features of gout in its various forms, and to the important subject of differential diagnosis. In the third section are presented certain investigations on the treatment of gout, chiefly as regards the solubility of sodium biurate and the process of solution of gouty deposits. The last part is devoted to the treatment of gout and gouty conditions. Here will be found directions as to the treatment of acute, subacute, chronic and irregular gout; details as to diet, local treatment, electric light, superheated air and other physical methods, as well as a discussion of the influence of alcohol and of mineral waters, baths, and climate upon the gouty processes.

In the present edition the new views as to the pathology and causation of gout are given full discussion. Many of the chapters have been rewritten, especially those on treatment and diet, on hydrotherapy and mineral waters. The book is an exceedingly practical, up-to-date treatise on a puzzling disease, by one who has thoroughly mastered his subject, as far as it is possible to do so in the light of present-day knowledge, and who knows how to impart his knowledge to his readers.

Vorlesungen uber Diätbehandlung Innerer Krankheiten vor Reiferen Studierenden und Aerzten. Von Professor Dr. H. Strauss in Berlin. Mit einem Anhang, "Winke für die diätetische Küche" von Elsie Hannemann, Vorsteherin des Haushaltungs-Lehrerinnen-Seminars und der Kochshule des Lette-Vereins in Berlin. Berlin: Verlag von S. Karger, 1908.

Dr. Strauss's book consists of fifteen lectures on the principles of diet in the internal diseases. Among others, the following lesions, functional and organic, are taken up; acute and chronic gastritis, disturbances of gastric secretion, gastric ulcer, diarrhea, constipation, intestinal parasites, renal diseases, gout, diabetes mellitus and obesity. In the treatment of gastric ulcer Dr. Strauss inclines to the low diet of Leube in preference to the high proteid diet of Lenhartz. He enters with sufficient fullness into the use of a salt-free diet in nephritis, into the indications for the use of rectal feeding, and into the value of artificial foods.

The appendix, written by the lady superintendent of a cooking school, occupies one-third of the book and translates into practical kitchen "recipes" the recommendations of the author. The quantities of foodstuffs used are translated into their equivalents in the term of proteids, carbohydrates, and fats, so that the physician is enabled to make up a menu answering theoretical food requirements with the least amount of difficulty. The book may be safely recommended to physicians and to those in charge of diet kitchens in institutions.

Mortmain. By Arthur Train. New York: D. Appleton and Company, 1907.

As the problem novel has concerned itself with almost every phase of modern life, one need not be surprised to find it seeking material in the field of surgery. The first story in this collection is rather out of the ordinary, and though quite impossible is sufficiently weird to hold one's attention. It is based on the discovery of a famous English surgeon, whose life is thoroughly absorbed in his art, and who finally succeeds in solving the problem of limb grafting. The first patient is a baronet, financially embarrassed and on the eve of ruin. When he is informed over the telephone that the man who holds his notes has been assassinated, he accidentally upsets a piece of bric-a-brac which crushes his hand, making amputation and grafting necessary. While under the anesthetic he dreams that the hand of the criminal that killed his enemy has been fastened to him, making a chain of circumstantial evidence which would convict him of the crime. He is also haunted by the fact that the man from whom the grafted hand was taken died in consequence. In addition to all this he loathes the foreign member, occasionally suffers physical tortures, and finds his own mental and spiritual characteristics changing so that at times he is dominated by criminal impulses. The other stories in the volume are readable, but possess no special medical interest.

Lectures on Diseases of the Nervous System. Third Series. The Border-Land of Epilepsy: Faints, Vagal Attacks, Vertigo, Migraine, Sleep Symptoms and their Treatment. By Sir William R. Gowers, M.D., F.R.C.P., F.R.S.; Hon. Fellow R. Coll. Phys. Ireland; Member of the Soc. de Médecins Russes of St. Petersburg and of the Royal Soc. de Science of Upsala, etc. Philadelphia: P. Blakiston's Son & Co., 1907.

The well-known powers of accurate observation and wide experience of this eminent writer lead us to accept as authoritative his prolific writings which are justly very popular in this country. There is no more valuable book on epilepsy than that of Gowers, and the present little volume, on conditions "near to, but not of epilepsy," will be found of assistance in understanding and treating cases belonging to this, to most of us, very unfamiliar field. Illustrative cases of the various borderland conditions are reported; and the evidence, from which the facts and conclusions are deduced, that the affections under discussion are related to epilepsy, is briefly, yet clearly described, and throws much needed light on the nature of these affections. The term "vagal attacks" is a useful designation, by the author, and the chapter on this topic, together with some other portions of the book, constitutes a distinct contribution to the Hughlings Jackson hypothesis of the existence of lower level (medullary) fits.

A Text-Book of Surgical Anatomy. By William Francis Campbell, M.D., Brooklyn, New York. Professor of Anatomy, Long Island College Hospital; Attending Surgeon to the Methodist Episcopal, Swedish, and Bushwick Hospitals; Consulting Surgeon to the Jamaica Hospital. With 319 Original Illustrations. Philadelphia and London: W. B. Saunders Company, 1908.

The author of this volume has wisely started out from the following premises: (1) He has made no attempt to present all the anatomical data that could be gleaned from any and every source; (2) he has only selected those anatomical facts which have a practical bearing; and (3) due emphasis is laid on those structures and regions which have a peculiar interest for the surgeon. The result is that the volume before us is one which is eminently practical and satisfactory. In a general way the whole field of anatomy is covered, so far as is conformable with the above rules. Each section begins with a few pages dealing with the surface anatomy of the part. The various regions are then taken up in some detail, and almost every possible point that the surgeon can want information on is considered. Until quite recently the available works on surgical anatomy were few; but of late one publishing house alone has presented us with three new works on the subject, the volume under consideration being the latest, and in many respects the most useful of the three. Regional and Surgical Anatomy are not only the most valuable, but also the most interesting parts of the study of Anatomy, and are far removed from the dry details of ordinary first-year work. Students and practitioners alike will find this work entirely suited to their needs.

Alimentation et Hygiene des Enfants. Par J. Comby, Médecin de l'Hôpital des Enfants Malades. Troisième Edition. Avec 23 Figures. Paris: J. Rueff, 1908.

The author of the present volume is a well-known French pediatrist who has written a great deal on the subjects of infant feeding and hygiene. This particular book while not altogether popular in character is intended to serve as a work of reference to the laity, and for the most part the text is of a nature to be easily understood by the nonmedical reader. The range of subjects discussed is much wider than is customary in similar books and it should prove suggestive to physicians as well as instructive to the mothers whose children are under their care. While in many respects, especially in regard to the comprehensive question of milk modification, its teaching is quite different from that of the authorities in this country, the book represents very satisfactorily the views of continental pediatrists and is well worthy of the notice of all those interested in the hygiene of infancy.

Department of Neurology, Harvard Medical School. Contributions from the Massachusetts General Hospital, the Boston City Hospital, the Long Island Hospital, and the Neurological Laboratory. Vol. III. Boston, Mass., 1908.

Of the ten neurological contributions appearing in this volume, six are by Dr. E. W. Taylor. The others are by Drs. Putnam, Knapp, and R. M. Smith. Rare cases are reported and interesting topics are discussed such as: heredity in epilepsy, medical expert testimony, the psychotherapeutic movement, the plantar reflex, psychasthenia, etc.

MEDICAL SOCIETY OF NEW JERSEY.

Annual Meeting, Held at Cape May, N. J., June 18, 19 and 20, 1908.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. EDWARD J. ILL OF NEWARK, IN THE CHAIR.

Thursday, June 18—First Day.

THE morning was devoted to the reading of the reports of committees and the transaction of the business of the House of Delegates.

It was recommended that the Medical Society of New Jersey express its disapproval of the provisions of the Act of 1908 reorganizing the State Board of Health, because said act was retrogressive rather than progressive and because of the failure of the act to require that the administration of sanitary measures should be supervised mainly by persons having had medical training and experience in sanitation.

The afternoon session was opened by an invocation by the Rev. James McLeod of the First Presbyterian Church.

Addresses of Welcome.—FREDERICK J. MELVIN, Mayor of Cape May, and Dr. J. MORGAN DIX welcomed the members of the State Society, the former in behalf of the city, the latter in behalf of the county medical society.

Oration in Medicine.—Dr. WM. K. NEWTON of Paterson delivered this oration. He chose as his subject joint affections in childhood caused by infectious diseases. The term "Still's disease" accounted only for a very few arthritic affections in children. Although the disease known as rheumatoid arthritis in adults did occur in children, its clinical aspects and morbid anatomy differed. The term "rheumatism" should be eliminated from the nomenclature of joint affections. A large number of diseases should be included in the infectious arthritides. He confined his remarks to these latter. The cause of the trouble was a specific infection of one or another form, and might be simple or mixed. The onset might be with chilliness or pronounced chills. The large proportion were caused by an invasion by the diplococcus of Fraenkel. Many cases with exudate on the tonsils might result in a pure pneumococcus arthritis. Many cases seen by him were caused by a mixed infection, the pneumococcus and streptococcus. He related in detail such a case. The arthritis following scarlet fever was similar to that following erysipelas and acute rheumatism. He reported the case of a man with gonorrheal arthritis of both knee and ankle joints. Scurvy in children was always accompanied by arthritis. Many cases of infectious arthritis were due to intestinal intoxication. Other more common causes were considered.

Endothelioma of the Pleura.—Dr. HENRY S. PATTERSON of New York reported a personal case with autopsy, and a review of eighty-five other cases found in the literature. There were fifty-three males and thirty-two females. In twenty-four cases the whole pleura was affected. The nodular type more often than the diffuse type was met with when the whole pleura was not involved. In nineteen cases the opposite pleura was the seat of metastasis. The origin and source of this tumor was the subject of much controversy and he reviewed the various opinions published. The character of the fluid in the chest was hemorrhagic in sixty-five, clear in two, purulent in two, while in nine no fluid was found in the chest. In one case there was a change from sanguinolent to a purulent fluid. The trouble began with a sticking pain, cough, scarcity of expectoration and dyspnea. A striking feature was the absence of fever. The average duration of the disease was from six months to one year. The disease always terminated fatally. Tuberculosis and aneurysm must be excluded. The only way of making a diagnosis was by means of a microscopical examination of any tissues brought to the surface, either directly or by metastasis. The treatment of this incurable disease was palliative. Dr. Patterson said that he had been enabled to make a diagnosis because of reading Dr. Delafield's article on this subject which appeared in the MEDICAL RECORD in 1902.

Diagnostic Importance of Vomiting in Childhood.—Dr. ARTHUR STERN of Elizabeth read this paper. He divided the forms of vomiting as follows: (1) Cerebral vomiting; (2) prodromal and initial vomiting in acute infections; (3) gastroenteric and peritoneal vomiting; (4) vomiting in intoxications; (5) after excitement; (6) in cardiac insufficiency; (7) in cases of general neuropathy; (8) from miscellaneous causes. If they could throw aside that old superstition that vomiting was caused by teething, many lives would be saved. He reported two cases of erysipelas in infants, aged three and five months respectively, with fatal termination, and in both the prodromal vomiting was marked. The symptoms in connection with the vomiting make diagnoses of diseases possible and also enable one to distinguish the variety of vomiting.

Dr. HENRY L. COIT of Newark congratulated Dr. Stern in bringing before this Society in an interesting way such a trite subject as vomiting. There were certain classes of diseases in which vomiting was a prominent symptom. First, psychic or recurrent vomiting, which was practically a new disease. Again many cases of persistent vomiting have been attributed to a congenital pyloric stenosis. He emphasized a point of importance, the so-called "boric acid indigestion," caused by the free use of boric acid in the new-born and especially nurslings. He called attention to the projectile vomiting in cerebral disease.

Dr. P. DuB. BUNTING of Elizabeth said that vomiting should be considered as a symptom only, and not an entity.

Dr. JOHN P. REILLY of Elizabeth asked that a more careful study of vomiting be made.

Dr. NORTON L. WILSON of Elizabeth spoke of a form of vomiting occurring in connection with adenoids and hypertrophied tonsils and believed that in most cases it was due to a vitiated and increased secretion going down back of the pharynx rather than to the adenoids or hypertrophied tonsils.

Present Status of the Milk Problem.—Dr. ALEXANDER MCALISTER of Camden read this paper. He said that viewed from the present status of the milk problem every new step in the progress of substitute feeding of infants during the past fifty years only impelled them to a position closer to whole milk, milk for milk. That was where the circle began and that was its rational, logical and happy ending. Powders of cereal origin, condensed milk, sterilized milk, pasteurized milk, laboratory milk, home modified milk, *milk*, that was the whole round. The purport of his paper was not to favor a wholesale and indiscriminate return to the use of raw market milk. That would be unwise and the teaching unsafe. Nor was it the purpose to plead for the use of none but whole milk in general substitute feeding. That would often entail a needless hardship. But it was his object to urge the use of only ideal whole milk for the very young and delicate. In this practice simple methods of dilution or modification, possible in any home, yielded superior results because of the greater ease with which fresh whole milk could be digested. In every market this ideal milk could be had for the price of the searching. The market that fell short could not be shown up too early or too relentlessly.

Annual Address by the President.—Dr. EDWARD J. ILL of Newark delivered this address at the evening session, taking as his subject "Medical Expert Testimony." A witness, who was convicted of not having spoken the truth, was punished by the law. The expert could not

be prosecuted for having expressed an opinion, though it might be a falsehood, and was commonly contradictory to that of any other expert. The people knew that, as a whole, expert witnesses were honest men, otherwise they would hesitate to trust their lives into their hands. But they also knew that the testimony of the medical expert before a court of law was a purchasable article, bought and sold for dollars and cents. The court and the jury knew this likewise and the fact was bewildering to the people. They knew that the defendant could receive the services of as many doctors as his bank account would permit. Their opinion was the plaything of counsel on either side. He quoted the argument of Judge Cowing suggesting changes along the following lines: "First, paid experts are now partisan. The jury sees them coaching the counsel, who is responsible for their payment, as to questions to ask opposing experts, and the jury concludes that the testimony is not valuable. Second, the quality of the expert is not sufficiently looked into and insisted upon now. Lawyers and some judges think that the greater the number of experts on their side, the stronger ought their case to be. Third, it is too often the custom now to drag in too many experts on both sides. The jury is confused. Fourth, it is not fair to allow medical experts to give opinions based upon purely hypothetical questions." The courts could give no relief because the laws were inadequate. He said the chance of obtaining an early change in the method of securing expert testimony in New Jersey was not great, unless they took the matter in hand as a society. They had nothing to hope for from the courts. They were impotent in the matter. They had nothing to hope for from the bar for it was taking an important prerogative from them, by which they were able in the past to mislead the jury, or at least to weaken the argument of their opponent. They had little to hope for from the Legislature because their influence was almost nil as compared to that which the bar exerted. They must act in self-defense.

Oration in Surgery.—Dr. Maurice H. Richardson of Boston delivered this oration, "When Shall the Physician Distrust His Own Judgment in Surgical Matters?" He believed that a man entering upon practice could do nothing more effective in establishing that practice than to follow strictly the advice of one of his students: "Always consider the patient's welfare first and your own last." All made errors, he freely admitted; but he contended that the errors in surgery in the hands of those qualified to practise surgery were very insignificant compared with the successes. It became one to admit the errors with the greatest possible frankness that one might be able to bring into sharp contrast with them the successes, and that one's words might have as far as possible a judicial effect. In external pathology the errors which he saw most frequently were the result of a too favorable prognosis, based upon a wrong diagnosis. He said he had seen so many mistakes in the diagnosis of tumors which were to him glaringly conspicuous that he could not but speak strongly upon the subject. It was a conservative estimate, he was sure, to place the number of operable new growths allowed to go from a stage that was favorable to operation to one that was unfavorable or hopeless, at at least ten per cent. By far the largest proportion of errors were in the hands of physicians who were not experts in the diagnosis of tumors. Errors in the diagnosis of tumors were common. That his hearers and readers might appreciate the difficulty of accurate prediction, the frequency of errors, and the impossibility of always avoiding them, he referred briefly to a number of mistakes he had made. The older one got, the more charitable one felt toward error. He said he knew of no more intolerant physician than the man who was just beginning his practice, and he knew of no more tolerant and charitable physician than the man who had had many years of intimate contact with disease. Neoplasms affecting the long bones should always excite a suspicion of malignancy, no matter who made the diagnosis of benignancy, and a suspicion so strong as to indicate operation if that suspicion was entertained at an operable stage. While his experience in operative surgery for trivial functional disturbances led him to question with the greatest care the indications for operation and usually to decide against operation, similar experience with neoplasms had led him toward extreme radicalism both in benign and malignant disease. The physician, whether expert or not in the treatment of neoplasms of all kinds and in all places, should always distrust his prognosis except in a prognosis based upon evident inoperability and impending death. Even when the diagnosis of hopelessly inoperable cancer had been made, not a few examples of mistaken diagnosis could be given, mistaken diagnosis on the part of the most experienced followed by non-operative recovery. The interpretation of abdominal pain required great skill and experience. The error he attributed to a functional disturbance, a pain, that was really dependent upon an organic lesion. The physician must distrust his judgment when he called abdominal pain of little or no moment. Probably most of the fatal emergencies of abdominal disease could be successfully resisted if abdominal pain were immediately heeded. All the infections would be at once discovered were the pain that they cause immediately and accurately interpreted. The physician always encountered these emergencies first. It was for him to make his diagnosis and his prognosis. In making them he must never forget that a favorable prognosis, based upon a wrong interpretation of acute abdominal symptoms, chiefly pain, meant a loss of the main chance for recovery. The fatalities in acute abdominal disease then were owing to a non-recognition of early infections, and especially of the significance of pain. The accidents of convalescence seemed to him the hardest to bear with philosophy, especially if they were avoidable accidents. The relations between the general practitioner and the surgeon had always been, and always would be, close. Their interests were the same, and they should work in harmony, real, cordial downright friendship. What concerned the welfare of the one, equally concerned the other. Some of the postoperative accidents came with awful unexpectedness, and he recalled some cases in his experience, one a case of pulmonary embolism, another a case of postoperative phlebitis. The chief thing to guard against in convalescence was hemorrhage. The subject of hemorrhage raised in his mind many spectres of unhappiness and gloom; he said he had passed many an hour fighting against the inevitable; or, worse than all wavering between operative and nonoperative treatment in a case of suspected hemorrhage. Fortunately, most postoperative hemorrhages were easily controlled if they were discovered in time. The common experience in our profession was for the surgeon to shift to the shoulders of the physician the responsibility of most surgical failures. Surgeons owed so much to the general practitioner that they should be generous, particularly in that form of generosity which assumed as far as possible the burdens of failure. Speaking as a surgeon, he had learned to distrust himself in surgical matters; his daily life was a constant endeavor to perfect himself in those branches of the surgical art in which he for one was most open to distrust. Chief among those were diagnosis and indications for treatment, with the greatest emphasis laid upon the contra-indications to surgical operations. Perhaps the most frequent error on the surgeon's part was in the diagnosis of gallstones. He recalled a few cases in which explorations had failed to show them after a pretty positive diagnosis. Perhaps once in fifty operations they found no gallstones. The successes of surgery amazed him. The more intimate and correlative the two great divisions of medicine, the more effective and brilliant will be the results of their interdependence. What was needed was as intimate a re-

lationship between medicine and surgery as could possibly be brought about, a generous and friendly intimacy.

The Influence of Overweight and Underweight on Vitality.—Dr. Brandreth Symonds of New York, Medical Director Mutual Life Insurance Company, read this paper (to be published in a later issue).

Report of a Case of Excision of the Stomach for Carcinoma.—Dr. Edward Staehlin of Newark made this report and presented the specimen. The growth involved the entire pylorus and there was a complete stenosis. The patient was a woman, fifty-three years of age. She suffered from indigestion for three years, and this became more and more distressing. Soon all solid food was gradually eliminated. Six weeks prior to operation she lost weight at the rate of three pounds a week. She became much emaciated. The abdomen was very flabby. In the epigastric region a soft and smooth mass could be felt. It was movable. A diagnosis of carcinoma of the pylorus with stenosis was made. The pylorus and five-eighths of the stomach was removed. She made an uneventful recovery. To-day she was in Europe with normal weight and appearance. Her endurance was good. She ate often but little.

Tetanus, Its Prevention and Treatment.—Dr. J. Harris Underwood of Woodbury read this paper. A clear description of this disease was given in the sixteenth century by Ambroise Paré. Sternberg in 1880 produced experimental tetanus in animals, and threw new light on its etiology. He gave a description of the disease. The bacillus remained at the site of injury and there manufactured its toxin. A thorough disinfection of the wound should be made with bichloride of mercury (1-1,000) or a solution of carbolic acid. The latter should not be used in pure form because it coagulates the albumin and so helped in defeating the object aimed at. The treatment aimed at controlling the spasm, overcoming the effects of the toxins and supporting the patient. He closed his paper by a relation of cases.

Friday, June 19—Second Day.

Annual Address by the Third Vice-President.—Dr. Thomas H. Mackenzie of Trenton made this address, choosing for his topic "A Brief Review of Hernia, as Understood and Treated at Different Epochs by the Past and Present Masters of Surgery." Up to the eighteenth century the treatment of hernia was in the hands of itinerant quacks and it was said that one of these was in the habit of feeding his dogs with the organs removed. It was said that one in five was afflicted with hernia. He gave a brief description of the crude methods practised by ancient surgeons in this country and abroad. He told of the evolution and trend of medical thought from the most remote periods to the present time, and considered the truss as a retaining and curative apparatus. He spoke of the etiology of inguinal hernia as bearing upon the technique in obtaining a radical cure. Among the predisposing causes was the congenital or preformed sac. This occurred in seventy-five per cent. of male subjects; in the other twenty-five per cent. various degrees of patency might be found. Other causes were inordinate size of the normal outlet of the inguinal region, distension of the abdomen by ascites, etc. Exciting causes included lifting, jumping, and whatever caused increased abdominal pressure. Dr. Coley reported 2,032 cases of inguinal hernia operated on with but one death. He also reported 1,185 cases of inguinal hernia operated on by the Bassini method with but nine relapses. Dr. Mackenzie reported 280 cases of hernia operated upon by him; there were ten umbilical, five femoral and 265 inguinal. In forty of these cases the operation was done because of strangulation. A radical cure should be obtained in 99.7 per cent. of the cases. Among the things necessary for success were the following; primary union was a *sine qua non*, and this meant asepsis; the sac must be dissected and completely removed; the funicular process must be removed; the conjoined tendon must be sutured to the under part of Poupart's ligament. The brilliant result obtained by the present-day methods was as true for femoral as it was for inguinal hernia.

Acute Intestinal Obstruction.—Dr. Robert M. Curts of Paterson read this paper. The recognition of the condition within thirty-six hours was the object of the paper. There was no disease which called for such refinement of diagnostic acumen as in this stoppage of the intestinal canal. From an anatomical point of view there were few points where the affection might not occur. He briefly mentioned volvulus or twisting of the intestines, especially the sigmoid; stricture of the bowel resulting from previous lesion or a strangulated hernia; fecal impaction, usually in the large intestine; gallstones; peritonitis with adhesions; bands; hernia and all forms of external hernias; intussusception. As regards the relative frequency he quoted Gibson's figures as follows: strangulated hernia, 354 cases with mortality of 37 per cent.; intussusception, 187 cases with mortality of 50 per cent.; bands, 186 cases, with mortality of 41 per cent.; volvulus, 121 cases, with mortality of 84 per cent.; Meckel's diverticulum, 42 cases, with mortality of 62 per cent.; gallstones, 40 cases with mortality of 57 per cent.; apertures, 34 cases with mortality of 62 per cent.; foreign body, 16 cases, with a mortality of 25 per cent.; diaphragmatic hernia, six cases, with a mortality of 100 per cent. He confined his remaining remarks to a consideration of acute intussusception, with the chief diagnostic points of bloody mucus, constant tenesmus, tumor, etc. So soon as diagnosed immediate operation was called for.

Dr. T. W. Harvey of Orange said that intestinal obstruction should be considered a surgical disease. Early operation for intestinal symptoms had eliminated many cases of intestinal obstruction. In his experience, to be successful, operation must be done within twenty-four hours after obstruction. An important point was in deciding whether or not a complete or incomplete operation should be done.

Clinical Features and Treatment of Acute Perforating Gastric and Duodenal Ulcer.—Dr. Ellsworth Eliot, Jr., of New York read this paper, which was based upon ten cases, eight of duodenal and two of gastric perforating ulcer. Gastric ulcers occurred more frequently in women, and between the ages of 20 and 30 years. Duodenal ulcers occurred more frequently in men, particularly those of alcoholic habits, and between the ages of 30 and 40 years. Always search for a second ulcer on the posterior surface of the stomach, directly opposite the one situated on the anterior surface. The symptoms prior to perforation depends upon the country. In this country 68 per cent. had a prior history; in the balance perforation occurred without history. Abroad the proportion was much less. In five or ten per cent. the perforation occurred without prior history, while in 90 per cent. there was some history. Vomiting occurred in two-thirds of all cases. Dr. Eliot demonstrated his method of making a physical examination of a patient with either form of ulcer. Blood count, the leucocytosis, was of particular value in obviating a needless operation. A patient with leucocyte count of 20,000 or 30,000 when promptly operated on would get well; whereas if the count was 15,000 or under he would probably die when operated upon. The treatment of the perforation required an early laparotomy. A general anesthetic should be given, chloroform by preference. The site of perforation should be freely exposed. The prognosis was very good if the operation was done within twelve hours. The perforation was closed by many ways, such as a mattress suture, or purse string suture reinforced by a Lembert suture. Some surgeons use adjacent viscera in closing the opening. An excision of the ulcer he believed to be a dangerous procedure. The treatment by gastrostomy he condemned. The amount of cleansing of

the peritoneal cavity depended upon the amount of soiling. He preferred using irrigation rather than sponging. The less drainage the better. But with general peritonitis, drainage must be used above and below. He brought up the question whether or not a gastroenterostomy was necessary as an addendum. He believed it was in cases where stenosis existed. It also prevented undue tension upon the sutures, and tended, too, to prevent hemorrhage. A gastroenterostomy was said to aid in the prevention of a secondary perforation. In a review of the literature he could find but two cases in which the time limit was given in relapses after operation; *i. e.*, how long the patient was free of symptoms. In one it was one year, in the other it was four years after operation.

Dr. Gordon K. Dickinson of Jersey City spoke of the constitutional states of the patients in these cases, because of the pouring into the duodenum of noxious or toxic materials. The treatment of these ulcers was largely preventable; if the patient was anemic and had gastric or duodenal symptoms he should be carefully watched.

Dr. James S. Brown of Montclair said his personal experience was with but six cases with a mortality of 70 per cent. The cases were seen too late. The last patient was treated for six days by Christian Science before operation.

Remote Pain Following Abdominal Operation.—Dr. William E. Darnall of Atlantic City read this paper. It was his opinion that abdominal pain was transmitted by the nerves in the parietal peritoneum. It was claimed that a large proportion of the cases of constipation and flatulence was due to adhesions following abdominal operations. The bowels always should be handled as little as possible in order to eliminate the danger of peritoneal adhesions as much as possible. In abdominal surgery the operation should never be attempted unless the abdominal muscles were completely relaxed. No raw surfaces should be left exposed if adhesions were to be prevented.

Dr. Elsmore Stites of Bridgeton said that in estimating the diagnostic value of pain they should remember that pain varied greatly in different individuals. The character and location of the pain should be carefully considered and particularly whether accompanied by fever or not. He believed that too often they were led to attempt to relieve by operative procedures conditions that were entirely due to nerve exhaustion.

Reflex Gastric Symptoms, a Factor in Surgical Disease of the Abdomen.—Dr. John P. Reilly of Elizabeth spoke of the importance of reflex gastric symptoms in the early recognition of pathological lesions. Because of these symptoms mistaken diagnoses were often made; gastric symptoms were present at times when the lesion was not in the stomach. Many times diseases existed in the gall bladder, the duodenum, and appendix with reflex gastric symptoms. One man had reported forty-nine gall bladder cases, and in every one the most prominent symptom was gastric disturbance.

Election of Officers.—*President*, Dr. David St. John of Hackensack; *First Vice-President*, Dr. Benjamin A. Waddington of Salem; *Second Vice-President*, Dr. Thomas H. MacKenzie of Trenton; *Third Vice-President*, Dr. Daniel Strock of Camden; *Corresponding Secretary*, Dr. Harry A. Stout of Wenonah; *Recording Secretary*, Dr. William J. Chandler of South Orange; *Treasurer*, Dr. Archibald Mercer of Newark. The next meeting will be held at Cape May on the fourth Wednesday, Thursday, and Friday of June, 1909.

Institute for Inebriates.—Dr. Alexander Marcy, Jr., offered the following resolution, which was carried unanimously: *Resolved*, That the Medical Society of New Jersey places itself on record as being in favor of the establishment of a State institution for the care and treatment of inebriates.

Acute Anterior Poliomyelitis, with Special Reference to the Recent Epidemic.—Dr. David T. Bowden of Paterson read this paper. He briefly reviewed the recent epidemics and gave a classical description of the disease.

The Importance of Studying the Condition of the Heart Muscle in Various Diseases.—Dr. Hobart A. Hare of Philadelphia read this paper, dealing with the muscle changes which often occurred, so often that in all probability all persons presented them in more or less degree at some time in their lives, usually in advanced years. Not rarely patients presented themselves with symptoms which were not distinctly cardiac, and it was only by careful heart study that they were able to determine that the general impairment of mental and physical energy was dependent upon a poor circulation. The pulse was found to be small and feeble, the tension unduly low, and the heart sounds poorly accentuated. The condition giving rise to this state was usually an excess of nerve-exhausting work or an illness which had sapped the vitality of the patient. Closely associated with this class of patients was that class who suffered from prolonged feebleness of the heart after an attack of true influenzal infection. What the exact changes in the heart were under these circumstances had not been determined, but they saw them clinically. Such patients often suffered from faintness and precordial distress in exertion. They were pallid and relaxed, and really needed rest and hydrotherapeutic measures more than the internal use of drugs. Dr. Hare was often impressed with how little attention was paid to the feeble heart of tuberculosis. He called attention to a sound not described in the textbooks and characterized by a peculiar vibrating, tense sound resembling somewhat the sound "ching" when somewhat muffled, and which seemed to him to be due to imperfect systole with vibration of the chordæ tendineæ due to feeble and weak heart muscle. The condition of the heart as the result of overstrain he divided into three parts: The condition immediately after acute overstrain, the condition after chronic overstrain, and the final condition often met with months or years after these types of strain had passed away. He reported the case of a wealthy merchant who concluded that his loss of vigor depended upon lack of exercise; he took a long race on the road against his son and nearly fell to the ground after alighting. He refused to go home except on his bicycle, and on reaching home went to bed with a dilated, feeble heart, from which he speedily died. His heart needed rest and not exercise. Such hearts often sounded when they listened to them as if they were beating vainly in an endeavor to accomplish something and were well described by calling them "pigeon-wing hearts," hearts that were beating violently as did a pigeon's wings when it first took a hurried flight or was in a cage. It was remarkable how often they met with hearts which were distinctly damaged by prolonged nervous worry. The victims of great mental strain not rarely have developed actual organic and degenerative changes in the heart muscle and blood vessels. The late Dr. Pepper, who died of angina at the age of fifty-five years, and whose coronary arteries were wonderfully sclerotic, while the circle of Willis was wonderfully calcareous, illustrated this very well, yet he never drank to excess, nor was he the subject of gout or rheumatism. Here was a man who, with vast mental responsibilities, lived two lives in less than the years usually given to one, and so produced cardio-vascular changes many years before they might have developed in the course of ordinary natural causes. That these changes were the result of nerve strain more than infection or exposure was shown by the frequency of those states in the officers of great corporations and their infrequency in the men who performed manual labor. There can be no doubt that one cause of this lay in the great increase in heart action required by mental effort, accompanied as it was by nervous waste without the compensation of long periods of

rest, of outdoor exercise and fresh air. The large demands upon the circulatory system for an execess of blood to maintain the excessive activity began to call upon the blood vessels so that they diminished their caliber under the high nervous tension of the individual, and this again made demand upon the heart, with the result that the final period of life, above sixty-five years, according to Benecke, was hurried upon a man who became prematurely aged, for after this age the fibroid changes coincident with advanced years resulted in an arterial rigidity which not only increased arterial tension at all times, but particularly so whenever any exertion was made, thereby throwing a very great strain upon the heart, which was correspondingly unable to meet it, although it attempted to do so by the hypertrophy of old age, which made it equal its size at forty-five years.

Dr. Philip Marvel of Atlantic City said that there had been referred to: (1) The changes arising within the circulation; (2) the changes primarily outside the circulation; (3) the changes that seem to have their origin primarily within the nervous symptoms or faulty disturbances of nutrition. In the second class there was a mixed condition, a primary involvement of, the circulation as well as the nutritive changes taking place simultaneously with the sclerotic changes.

Dr. Martin J. Synnott of Montclair said that myocardial changes respond to the carton dioxide baths as administered at Manheim, Germany. He had six patients treated at the artificial Manheim, Watkins Glen, N. Y., and with good results.

Alexander Marcy, Jr., of Riverton emphasized the importance of rest in the treatment of myocardial cases.

The Psychic Element in Medical Practice.—Dr. Linn Emerson of Orange read this paper. Most of general practitioners were grossly and harmfully ignorant, not only of the subject of psychology, but of all the sciences which at best could be said to be but in their infancy. The science of medicine had but recently emerged from the ignorance and superstition of the dark ages. There had always been associated with the healing art a certain mysticism. The unprincipled quack, by the very emphasis of pretended knowledge and promises of cure often brought about a restoration to health where the more skilled but more conscientious practitioner had failed. If the ignorant irregular could bring about so many cures by these methods, how much more should be accomplished by the scientific, careful, conscientious man. Many physicians refused to avail themselves of these means at their disposal, having no desire to be designated either a quack or a liar. The truth should be spoken at all times, and the successful physician must sometimes be a most skillful prevaricator. A promise to benefit or cure made in all hope and sincerity might eventuate a falsehood but not necessarily a lie. Many practitioners who were taking advantage of mental therapeutics and getting wonderful results thereby, were doing it unconsciously. The results accomplished by electrotherapeutic measures, massage, vibrators, fitting of glasses, gynecological tinkering, or even by some operations, were as much due to psychic as to material methods. The success of Christian Science and mental healing was undeniable, and the neglect of this phase of the healing art on the physician's part was in some measure responsible for their existence. The remedy would seem to be higher educational requirements for admission to the medical ranks and a more careful study of psychic phenomena by all members of the profession.

Dr. W. M. Leszynsky of New York believed that a discussion upon this subject should be more intellectual than emotional. There was an increasing majority of men in the medical profession who deem the present psychotherapeutic agitation worthy of careful consideration and analysis. Psychotherapy should not be characterized as a method confined to certain forms of psychological analysis, persuasion, and hypnotic suggestion to the subconscious mind. Within its sphere one must include isolation, educational measures, physical, moral, and intellectual, healthful occupation, and diversion, encouragement, etc. The man who, without discrimination, thoughtlessly told his patient that there was no hope for him, was not a desirable representative of intelligent psychotherapy. Special methods of psychotherapy, such as the reeducational method of Dubois, Freund's analytical method, and hypnotic suggestion, all had their limited fields of usefulness. But psychotherapy alone could not successfully supplant a rational plan of modern medical treatment adapted to the individual, and based upon regulation of habits, and occupation, hydrotherapy, physical exercise, etc., in conjunction with moral management through suggestion, persuasion, educational and disciplinary measures. Psychotherapy was by no means a panacea in the phychoneuroses, its usefulness being limited.

Saturday, June 20—Third Day.

A Résumé of Modern Methods of Treatment for Posterior Displacements of the Uterus.—Dr. J. Watson Martindale of Camden read this paper. By displacement he meant a permanent departure from the normal position. Among the congenital causes, there was a backward displacement of the axis or curving forward of the axis itself. This was usually accompanied by an imperfect development of the ovaries and tubes, as well as the uterus itself. Among the acquired causes, he mentioned strains, tumor pressure, contracting adhesions, laceration of the pelvic floor, subinvolution after labor, congestions, loss of muscular tone, faulty dress, etc. He did not believe one could have a prolapse of uterus without a downward displacement. One might have a retroverted uterus without symptoms whatever. He quoted some gynecologist, who said that so long as a woman had her uterus in her abdomen she was all right; but as soon as it was in her head, she was all wrong. Drawing down the cervix with a tenaculum usually enabled one to restore a retrodisplaced uterus, if nonadherent to its normal position. If the uterus was bound down by adhesions it had better be left alone, unless one was prepared to do a section. In cases of procidentia it was impossible to effect a cure without repairing the pelvic floor. The subject of his paper was to point out the advantages and disadvantages of each method of treatment. The treatment primarily aimed to repair the pelvic floor; second, to bring the uterus into a position of anteflexion. The technique of the Alexander operation was described and illustrated by colored drawings. He then described the technique of vaginal fixation with an anterior colporrhaphy, an operation which was indicated in cases of cystocele in patients beyond the child-bearing period. In this operation there should be a repair of the pelvic floor. The results in the cases he had seen were excellent. He then described ventral fixation, which was indicated in women with procidentia, and who were beyond the child-bearing period. An anterior colporrhaphy and amputation of the cervix should be done as well. This operation was not so successful as the vaginal fixation. Other operations for shortening the round ligaments were described. Where the round ligaments were made to pierce the fascia, one would think it would invite hernia; but Dr. Martindale had never heard of such a sequela. He closed by describing the retroperitoneal shortening of the round ligaments.

Dr. Edward Staehlin of Newark said that in women in or beyond the menopause with complete procidentia he recommended a vaginal hysterectomy rather than the methods described by Dr. Martindale. From the fact that so many methods are described for the restoration of the pelvic floor showed that the present means were inadequate. An anatomical repair of the perineum should be aimed at. The binders in vogue at the various maternity hospitals were causative factors in the production of re-

troversions of the uterus. The use of the sound was often a pernicious habit.

Dr. Edward J. Ill of Newark had had a larger experience with the Gilliam operation. He had done 500 operations with less than ½ per cent. of failures, a remarkable showing. The fibroperitoneal adhesions were very strong. Mayo had drawn from an inch to an inch and a half of peritoneum in, and Dr. Ill thought that Dr. Mayo must meet with many cases of subfascial hernias. When Dr. Ill saw Dr. Mayo operate, the latter had done this operation on 245 cases.

Dr. Frank D. Gray of Jersey City referred to the good results he had had with the Webster operation for retrodisplacement. In two cases he had met with an imprisoned ovary under a retroflexed uterus. This could not be done without dissection, which should be done more often.

Dr. Thomas W. Harvey of Orange referred to curing retrodisplaced uterus by advising the woman to become pregnant and giving proper subsequent care.

Dr. Edward J. Ill of Newark called attention to an article on this subject by the late Dr. Paul F. Mundé, in which were given statistics showing that but 3 per cent. get well.

The Drink Habit and Its Treatment.—Dr. Charles A. Rosenwasser of Newark read this paper. He said that to the learned men of the day it was apparent that the use of fermented liquors was injurious to the health and morals of the nation, and a vigorous campaign in the cause of temperance had been begun. In attempting to cure a patient the greatest obstacle one met was the nature and make-up of the patient. He could not see himself as others saw him, and should, therefore, be approached very tactfully. The treatment must cover months, and consisted in studying the patient and applying in each case the remedies called for. The underlying cause for the craving of alcohol might be difficult to locate. There was no one remedy that would cure all cases. The drink habit could not be cured against the will of the victim; and, without his cooperation, a cure was an absolute impossibility. In most cases the treatment of the drink habit resolved itself into nothing more nor less than the treatment of an aggravated case of neurasthenia. One could achieve success in a gratifying number of cases if one would go about it in the right way. Dubois said, "The nervous patient was on the path to recovery as soon as he had the conviction that he was going to be cured; he was cured on the day that he believed himself cured." This statement held good in the drink habit more truly than elsewhere. The treatment in the beginning must be purely psychic. Having won the confidence of the patient, the practitioner must make good his promises. This could be done in a surprisingly large number of cases without requiring the detention of the patient. Treatment, to be effective, had to be systematic. The speaker's patients reported three times daily during the first two or three days, then twice a day for the balance of the first week; during the next three weeks they reported once daily. He then saw them once a week for a month; then once every two weeks. Then once a month for as long a time as he could get them to come. He did not tell the patient what medicine he was receiving, and gave every dose himself as far as possible, to be sure that instructions were being carried out and to prevent self-drugging, which was very prone to develop in this class of patients. He always urged the patient to stop drinking entirely at once, and not to "taper off," as that was like cutting off a dog's tail by inches. He secured free purgation at the outset by compound cathartic pills, fortified with podophyllin, and kept the bowels rather loose for the first few days. He gave atropine grain 1/1000, three times daily, for two or three days, then diminished the dose, and discontinued at the end of the first week unless further treatment was indicated. He also gave arsenious acid, 1/20 grain, three times daily for a few days, then twice daily for the balance of the week. Sedatives and hypnotics where conditions called for. For vomiting due to alcoholic gastritis there was nothing to compare with calomel given in ¼-grain doses every half hour for ten doses, and followed five hours after the last dose with a Seidlitz powder. For gnawing in the stomach, he gave quassia or milk of magnesia. During the second and third weeks he gave 15 grains of red extract of cinchona suspended in glycerin and water every night and morning. Beginning with the fourth week, and continuing for several months, his patients received a tonic pill containing phosphorus, strychnine, iron, arsenic, quinine, and cascara. All medication was given by the mouth, except apomorphine, which was given hypodermically. The diet should also receive attention. The patient should be encouraged to eat freely, and at short intervals, large quantities of wholesome, nourishing food. Meat should not be taken more than once daily; the closer these patients adhered to vegetable diet the better. He told the patients to keep their stomachs busy digesting food, and they would not bother them for drink. He advised them to take some slight nourishment on the slightest sensation of fatigue or emptiness.

Dr. Livingston S. Hickley of Newark said that many continued drinking without disastrous results. The effect of the drink habit upon the progeny was debatable. The death rate due to alcohol was worthy of consideration. Why men took alcoholic stimuli was largely a question of individualizations. Forty million of our population had been restrained from drinking because of the popularity of prohibition. He believed the real solution of the drink problem rested in education, beginning with the child. A bill was introduced in 1903 for the purpose of establishing a State hospital for inebriates, passed the Assembly, but failed to reach the Senate. The name of this institution was to be the New Jersey Psychopathic Hospital.

Dr. Alexander Marcy of Riverton believed the paper needed no discussion. One important thing to ask was the duty of the State in this matter. The State owed to these patients and their families something more than the regulation of the sale of intoxicants. Probably the time was not ripe for the prohibition of the sale of any intoxicants in this State, but he hoped the time would soon come. Until such a time the institution of a State hospital for inebriates should be aimed at.

Study of Tropical Diseases.—A report of the Advisory Committee for the Tropical Diseases Research Fund has been issued as a bluebook. The revenue for last year was £3,075 and the expenditure £2,433. The Liverpool school employed its grant for a lectureship in economic entomology and parasitology and has asked for a further grant. The committee has allotted an extra £500 to be applied definitely to work in connection with sleeping sickness, a program to be submitted in advance. In response to a similar application the committee has allotted an extra grant of £1,000 to the London School to establish a post entomology on condition that the entomologist shall make a collection of noxious insects of the colonies, a separate collection for each colony, to be kept in readiness for reference by colonial officials or doctors. In reply to a request of the Secretary of State as to sleeping sickness in Uganda, the committee has advised that the following measures be adopted: (1) Segregation of all persons infected in camps situated in places free from glossina; (2) removal of the apparently healthy from fly-infected areas, and (3) the clearing of such bush as would afford shelter for the fly at all fords, ferries, landing places and sources of water supply, for a limited area, such cleared areas to be kept free of bush and cultivated with low-growing crops which could not afford suitable shelter for the fly. Steps are now being taken to carry these recommendations into effect. In regard to the encouragement and systematization of research the bluebook states that a dispatch has been sent to the Governors of those colonies in which laboratories exist, suggesting the preservation of the results attained by research in those laboratories so as to make them accessible to the successive officers in charge.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

COSMETIC SURGERY (Second Edition). By CHAS. C. MILLER, M.D. 16mo, 134 pages, illustrated; cloth, $1.50. Charles C. Miller, Chicago.

INTERNATIONAL CLINICS. Edited by W. T. LONGCOPE, M.D. 8vo, 309 pages, illustrated: cloth. J. B. Lippincott Company, Philadelphia.

THE COMMON SENSE OF THE MILK QUESTION. By JOHN SPARGO. 12mo, 351 pages, illustrated; cloth. The Macmillan Company, New York.

AMERICAN PRACTICE OF SURGERY. By JOSEPH D. BRYANT, M.D., LL.D., and ALBERT H. BUCK, M.D. 4to, 1,010 pages, illustrated: cloth. William Wood & Company.

AN ABRIDGMENT OF PRACTICAL MEDICINE AND ALLIED SCIENCES. By J. CANDOR MCLAUGHLIN. 48mo, leather, 524 pages. J. Candor McLaughlin, Kansas City.

THE BACTERIOLOGY OF DIPHTHERIA. Edited by G. H. F. NUTTALL, M.D., Ph.D., Dc.D., F.R.S., and G. S. GRAHAM-SMITH, M.A., M.D. 4to, 718 pages, illustrated; cloth, $7.50. G. P. Putnam's Sons, New York.

THE BORDER-LAND OF EPILEPSY. By SIR WILLIAM R. GOWERS, M.D., F.R.C.P., F.R.S. 8vo, cloth, 121 pages; $1.25. P. Blakiston's Son & Company, Philadelphia.

PRACTICAL LIFE INSURANCE EXAMINATIONS. By MURRAY ELLIOTT RAMSEY, M.D. 12mo, 231 pages; cloth. J. B. Lippincott Company, Philadelphia.

NURSING THE INSANE. By CLARA BARRUS, M.D. 8vo, 409 pages; cloth. The Macmillan Company, New York.

GLIMPSES OF MEDICAL EUROPE. By R. L. THOMPSON, M.D. 8vo, 236 pages; cloth. J. B. Lippincott Company, Philadelphia.

THE SPECTROSCOPE; ITS USES IN GENERAL ANALYTICAL CHEMISTRY. By T. THORNE BAKER, F.C.S., F.R.P.S., 8vo, 130 pages, illustrated; cloth, $1.75. William Wood & Company, New York.

HERNIA; ITS ETIOLOGY, SYMPTOMS, AND TREATMENT. By W. MCADAM ECCLES, M.S. (Lond.), F.R.C.S. (Eng.). 8vo, 234 pages, illustrated; cloth, $2.50. William Wood & Company, New York.

MINOR MALADIES AND THEIR TREATMENT. By LEONARD WILLIAMS, M.D., M.R.C.P. 12mo, 404 pages; cloth, $2.50 net. William Wood & Company.

INJURIES OF NERVES AND THEIR TREATMENT. By JAMES SHERREN, F.R.C.S. (Eng.). 12mo, 310 pages, illustrated; $2.00 net. William Wood & Company.

PROTOZOA AND DISEASE. By J. JACKSON CLARKE, M.B. (Lond.), F.R.C.S. 8vo, 138 pages, cloth, illustrated; $2.50 net. William Wood & Company.

KOSMETIK. By Dr. E. SAALFELD. 8vo, 122 pages; cloth, $3.60; illustrated. Julius Springer, Berlin.

ROTUNDA MIDWIFERY FOR NURSES AND MIDWIVES. By G. T. WRENCH, M.D. 12mo, 324 pages; cloth. Oxford University Press, New York.

THE HISTORY OF THE STUDY OF MEDICINE IN THE BRITISH ISLES. By NORMAN MOORE, M.D, Cantab. 8vo. 202 pages, illustrated. Clarendon Press, Oxford.

A MIND THAT FOUND ITSELF. By CLIFFORD WHITTINGHAM BEERS. 8vo. cloth, 363 pages, $1.50 net. Longmans, Green & Co., New York.

LES PSEUDO-BACILLES ACIDO-RESISTANTS. By Le Dr. ANDRE PHILIBERT. Large 8vo, 142 pages; paper. G. Steinheil, Editeur, Paris.

LIFE INSURANCE AND GENERAL PRACTICE. By E. M. BROCKBANK, M.D. (Vict.), F.R.C.P. 12mo, 288 pages, half morocco. Oxford University Press, New York.

THE BLUES: CAUSES AND CURE. By ALBERT ABRAMS A.M., M.D. (Heidelberg), F.R.M.S. 8vo, 286 pages, illustrated; cloth, $1.50. E. B. Treat & Co., New York.

BRADYCARDIA AND TACHYCARDIA. By Prof. EDMUND VON NEUSSER. 8vo, 150 pages; cloth, $1.25. E. B. Treat & Co., New York.

ARTERIAL HYPERTONUS, SCLEROSIS AND BLOOD-PRESSURE. By WILLIAM RUSSELL, M.D., F.R.C.P. (Edin.). 8vo, 101 pages, illustrated; cloth. J. B. Lippincott Co., Philadelphia.

MANUAL OF SURGERY. By ALEXIS THOMSON, F.R.C.S., Ed., and ALEXANDER MILES, F.R.C.S., Ed. (Vol. I., General Surgery). 12mo, 808 pages, illustrated; cloth. J. B. Lippincott Company, Philadelphia.

MANUAL OF SURGERY. By ALEXIS THOMSON, F.R.C.S., Ed., and ALEXANDER MILES, F.R.C.S., Ed. (Vol. II., Regional Surgery). 12mo, 816 pages, illustrated; cloth. J. B. Lippincott Company, Philadelphia.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 4, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	374	150
Diphtheria	243	28
Measles	472	15
Scarlet Fever	244	23
Smallpox	—	—
Varicella	54	—
Typhoid Fever	37	8
Whooping Cough	17	5
Cerebrospinal Meningitis	—	2
Malarial Fever	—	—
Totals	1441	231

Health Report.—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending July 3, 1908:

			Cases.	Deaths.
SMALLPOX—UNITED STATES.				
Alabama, Huntsville	June	5–18	85	..
Mobile	June	7–13	1	..
Arkansas, Texarkana	Dec.	1–June 15	..	Present
California, Los Angeles	June	7–30	3	..
Oakland	May	1–31	12	..
San Francisco	June	6–20	11	..

THE STANDARD OF MEDICAL EDUCATION.*

BY HENRY B. WARD, PH.D.,

LINCOLN, NEB.

DEAN OF THE COLLEGE OF MEDICINE AND PROFESSOR OF ZOOLOGY IN THE UNIVERSITY OF NEBRASKA.

THERE has arisen in recent years a general demand that some attempt should be made to set a uniform standard of medical education and to pass upon the attainment of the individual who offers himself to the community as a practitioner. There are four agencies which have taken a prominent part in establishing standards for medical education, and it is worth our while to consider briefly each of them together with the part it has played and the part it may be expected to play both in the establishment of a legal standard and in the molding of public opinion. These four agencies are the American Academy of Medicine, the Councils on Medical Education, representing the various national medical associations, the State Boards of Licensure, both individually and collectively in their associations, and our own organization, the Association of American Medical Colleges.

The American Academy of Medicine was founded more than a third of a century ago with the expressed intention of raising the standard of medical education by requiring for membership in the body that the element of liberal culture represented by a college education must precede the professional training. During its history a prominent feature in the meetings of the Academy have been the symposia on medical education in its various phases and stages. The Academy deserves the honor of having first pointed out clearly and definitely that there was no system in the relations between the literary college education and the professional course, and that by virtue of this lack of correlation grave injustice was frequently done to the student having the better preparation.

The Academy, however, necessarily has no official influence; its power is the weight of public opinion, its influence will be measured by its ability to form and control public opinion. That influence will undoubtedly be great because it is working with the leaders and among the leaders of American life, the college graduates; and yet the purely ideal conditions which it sets forth are a necessary limitation to the scope of its influence.

The various medical associations have each appointed a council on medical education. In this movement the American Medical Association led the way, and its Council has achieved publicly the greatest prominence as well as accomplished the most work. By virtue of its organization and financial condition this Association has been able to give its Council opportunities which have never been shared by any body of the type in this country. Under the auspices of the Council there have been held thus far three annual conferences on medical education and there has been published a series of approximately thirty pamphlets setting forth the records of these conferences, the reports of committees organized under its auspices, and the results of inspections it has made as well as of examinations held throughout the country by various official boards. One must recognize the great importance of its work. No other organization could have carried out so extensive an investigation or have brought together and published for the estimation of progress in medical education such comprehensive statistical comparisons as it has given. It is to us a compliment of the highest character that the Council has reprinted so much of the results which have been obtained by our committees and reported to our Association. It is equally a matter of felicitation that various officials of this organization have been so generously welcomed in the conferences of the Council and that the reports by the chairman of our Judicial Council, presenting much that has been deduced from our experience, have received such favorable consideration at the hands of these conferences.

Even though it must remain a purely advisory body and have no legal status, the Council on Medical Education will undoubtedly exercise a strong indirect control over medical schools by its schemes of reports and inspections and by scattering broadcast the results of these inspections. It is sure to be a potent force in the development of medical education, and yet I may be permitted to point out one or two features which as now conducted involve great responsibility and furnish genuine possibility for doing injury in individual instances. The policy of the Council is formulated by a small number of individuals. One could not ask for any modification of this plan. The Association having placed upon the shoulders of a committee the responsibility, that committee would not be justified in shirking it or in failing to formulate and push with vigor such plans for the advancement of medical education as seem to it wise. The annual conference gives opportunity, to be sure, for the presentation of all types of opinion, but there will necessarily be a considerable personal element in issuing invitations to this conference, and, furthermore, even those who are invited to participate naturally feel themselves, as guests, somewhat constrained in the expression of their individual views. It is easy to see, consequently, that the publications of the Council represent very largely an individual trend of opinion, and

*Abstract of the President's Address delivered at a meeting of the Association of American Medical Colleges, held in Cleveland, O., March 16, 1908.

it would be strange if certain aspects of some question did not fail to receive their full representation; it would be remarkable if all points of view were equally well represented; it would be almost inconceivable that a certain line of development in medical education would not be preferred above others. While the process of evolution should be influenced in the right direction, it is questionable whether the limitation of the process should be left in the hands of so small a group of individuals, however broad and impartial these persons themselves may be. More than this, it would be strange, indeed, if in the development of a line of action the committee did not some time or another come in conflict with so strong a force or one so related to themselves or their organization by personal or official ties that their judgment or their action would be modified or restrained thereby. It has been said that in some instances they have failed to meet questions with absolute frankness, to apply the same rules to all institutions and sections, and to safeguard with the same care the interests of all schools. These minor difficulties are in no way chargeable to individual prejudice, inefficiency, or inattention, but rather are inevitably connected with the tremendous task they have undertaken.

Last year on the recommendation of President Kober this Association appointed a committee to confer with the Council and to seek a plan for cooperative action. Such a move cannot be too strongly commended or too vigorously prosecuted. The Association of Colleges should strengthen this committee by adding to its numbers and its powers, and by such expression as will indicate to the public and the profession that we at least are unalterably committed to cooperation with all influences for the advancement of medical standards.

State Boards of licensure under various names and with radically different powers and privileges represent the agencies in the various States which are seeking to enforce legal standards of medical training. They represent a distinctly higher average opinion than that of their own locality, and they differ from each other as widely as the geographical and temperamental differences of the States they represent. In a legal way they embody the results of a series of some forty odd experiments, amended from one to one hundred times under the influence of innumerable factors, political, professional, and social; and the real wonder is that they have been able to get together with as much of uniformity and energy as has been displayed by the American Confederation of Reciprocating, Examining, and Licensing Medical Boards.

It is no injustice to say that individually the State Boards are given the minimum possible requirements and are enforcing them with the maximum energy compatible with the conditions of their particular environment. This is the inevitable result of their political establishment and control. They have uniformly succeeded in accomplishing more than other politial agencies in the same territory. They have ruled with fairness and freedom beyond that which is practised in legislative assemblies generally, and if there are striking exceptions to this rule let it be remembered that those exceptions have been generally discountenanced both within the State and without it, and that State Boards are continually seeking and exercising reasonably strict control of local conditions. Yet since opportunities for local jealousy and for the establishment of limitations which accrue to the advantage of local interests, are constantly present, they are unfortunately sometimes employed. It is evidently difficult for such boards to maintain a membership constant enough to insure maximum efficiency or to act as conditions demand in the face of strong popular pressure.

In spite of local jealousies and legislative limitations State Boards have organized a powerful national association. They have established a mutual basis of qualifications for interstate recognition and indorsement of licenses, and have introduced reciprocity to a considerable extent. Their work has disclosed many often serious difficulties in the way of a uniform system and of cooperative action, but good sense and able leadership are demonstrating the purely temporary character of these obstacles to progress. It is a matter of general commendation that the Confederation has a basis of requirements covering the preliminary education which is practically identical with our own, and has adopted our requirements for graduation and our standard curriculum as its schedule of an approved medical course. Harmony and cooperation in action between the Confederation and this Association have already led to important advances in medical education, and should be encouraged in order to promote uniformity of standards and to relieve medical schools as far as possible of the unjust burdens imposed by "many masters of many minds."

It is not necessary to discuss in detail the relations of our Association to medical education. It has always included in its membership the large majority of the better medical schools in this country. At one time the lax enforcement of standards had raised a temporary doubt as to its position with reference to the better things in medical education; but the vigorous campaign of recent years has left no doubt of its present sincerity and activity in behalf of high standards. Such institutions as have felt that local conditions did not warrant their joining in the general advances of the Association have been considerate enough to retire from membership and to avoid embarrassing inquiries, so that it has been necessary but twice to suspend schools from membership pending an investigation into their actions. From the prompt response made to personal inquiries concerning possible violations of our standards I am individually impressed with the desire of college authorities to live up to present regulations and not only to correct accidental infractions of our rules whenever they occur, but also to prevent if possible any recurrence of such mistakes.

In many ways the Association is proving itself to be a potent factor in advancing standards of medical education and in benefiting thus every school of high ideals. While its membership includes colleges of different grades in many particulars, it is possible to assert that no distinctly low-grade institution is now on its list of members. I confidently maintain that all its colleges are self-respecting and law-abiding, and are seeking the best in professional education. There are still a few high-grade institutions in the United States which are not in membership, and the Association should instruct its Judicial Council to extend a cordial though dignified invitation to these colleges to join with us in the work of

advancing medical education on this continent. While heretofore the membership of the Association has been confined to the United States, yet the high grade of work done by some Canadian medical colleges is ample justification for extending to them a similar invitation in order by joint effort to give greater breadth and strength to the movement.

The position of the Association in the search for standards in medical education is found at neither extreme. It recognizes that an ideal is attainable only by the favored few, and also that no doubt always some colleges will set standards below its own. It is seeking the average standard, available for all institutions, even though some choose to cut under its minimum. It encourages advance above the limits it sets and has always had in membership institutions demanding much more than its minimum standards. In all its discussions it seeks not the optimum of limited attainment, but rather the reasonable minimum, below which standards are possible but not rational at the current stage of evolution in professional education.

Standards Proposed.—It is necessary to establish definite standards and to use these in measuring the position of medical schools. The constants which need to be determined in fixing such standards as are, first, those of the preliminary education, second, those of the professional training, and in both there are three elements to be fixed: the number of years required, the length of each course which is acceptable, and the amount and kind of work which should be demanded. Now these factors are to be considered not from the standpoint of the maximum or of the optimum, but with a view to determining the reasonable minimum. This does not in any way limit an improvement upon the conditions outlined, it does not hold down the stronger schools to the level of the weaker, it merely sets a standard for recognition below which the institution may not be regarded as acceptable. The fixing of such standards will unquestionably serve greatly to clarify the atmosphere and to advance the quality of medical education.

Association Entrance Requirements.—With regard to standard requirements for entrance to medical colleges there is as little agreement as in other matters. In the place of the meaningless expression a "high school course," this Association was the first to advocate the introduction of further regulations specifying the length and character of such a course. In the working out of this problem our present standard owes much to the splendid work done by the New York Board of Regents in systematizing and formulating the general scheme of public school education. Their results are as applicable to any other State as they are to the commonwealth for which they were formulated. We are also greatly indebted to the vigorous work of the education and State board authorities in Michigan. The result of these efforts finds its expression in the standard minimum entrance requirements of this Association. They guard the time element in providing for a full four-year high school course and protect against cheap work and insufficient training by specifying the fundamental portion of that course. As pointed out by Dr. Vaughan of the University of Michigan, Dr. Harison of Detroit, and Dr. Wheelock of Albany, this clearly unequivocal and thoroughly pedagogical standard is far in advance of any yet put into effect by any other agency controlling general medical standards. It is practically in accord with the well-enforced requirements of New York, Michigan, and Ohio which represent the leading influences in regulating medical entrance requirements to-day and also with those of the American Confederation of Reciprocating, Examining, and Licensing Medical Boards. It is certainly far ahead of the actual requirements in force in many sections of this country. There has been reason to think in the past that some of the colleges in the Association have applied these regulations with a mercy that was primarily characterized by its disregard of justice. To-day the matriculation records are open to general inspection, and colleges in membership invite scrutiny of their practices. It is not too much to say that no such clear or well-enforced standard has ever existed in medical education in the United States as the preliminary education requirements of this Association.

Preliminary College Year Proposed.—The new standard proposed in 1906 by the Council on Medical Education of the American Medical Association provides in addition to the four-year high school course a year of college work devoted especially to physics, chemistry, biology, and language. There are now 54 colleges which by the first of January, 1910, will require for entrance one or more years of preliminary college work in addition to the full high school training. It is rather early now to speak definitely regarding this plan, but an examination of the list of these colleges discloses certain interesting features. In the first place the list includes a group of institutions which now require two years or more of preliminary college work and which have evolved a rational adjustment of the general training in the collegiate department and of the professional training in medicine. They are the leaders in medical education, are distinctly bidding for the best students, and have expressed themselves by their general action as well as in their publications as desirous of educating the leaders in the profession.

When we consider the remaining institutions, namely those which have announced that at this future date they intend to require one year of college work to be devoted especially to physics, chemistry, biology, and language, we find a rather peculiar condition. In the first place, some of them do not even yet require the full high school course for entrance, and in at least one of these it is proposed to advance the time standard of preliminary requirements by a total of five years, while this advance is to take effect within three years. We also notice among the institutions which have set this standard that there are some which have dropped from membership in our own organization, avowedly or tacitly, because they were unable or unwilling to abide by the standards which we had set, and to furnish documentary evidence in the form of a detailed certificate by the college authorities covering the entrance requirements of all students matriculated within the year. There are further among the number of those which have announced their intention of requiring this year of preliminary work such institutions as have been openly charged by various authorities with having violated previous standards of entrance requirements. In the face of these facts it is but natural to think that the announcement of their conversion

to the doctrine of advanced entrance requirements is not altogether disinterested.

On the other hand we find that certain most conservative and most stable standard medical schools have refused to consider this new limit of entrance requirements, and some of the reasons which have been adduced for their refusal are thoroughly tenable. The medical institution which is a part of a great university, and which is thus intimately associated with a department of arts and sciences, can set such an entrance requirement and can enforce it; for it has the means ready at hand to provide for the additional training of those who would enter and yet who are deficient either in whole or in part of the required college work. The isolated medical school, however, finds itself necessitated to adopt one of two courses: either it must accept anything in the way of college work which bears that label and have in its classes even a greater hodge-podge than it has at present, or it must itself provide facilities for one full year of college work. The second option is, I believe, most earnestly deprecated by all who have at heart the interests of general education. Conditions in the medical school are not such that the training of the literary institution can be given in any other than purely formal fashion. The distractions of the large amount of professional work and the lack of associated general courses will inevitably tend to dampen the enthusiasm and divert the attention of the student from his elementary studies. Furthermore, adequate provision for such a course is expensive, and unendowed institutions cannot hope to offer it in any other than a perfunctory and superficial manner. In the hands of the isolated medical college the additional year would become an obstacle to real progress, a disadvantage both to the institution and to the student. Most probably the plan would result merely in diluting the present work of the course, and if anything was really added it would be at the clinic end of the curriculum.

The other option presents practically equal difficulties. As I have already indicated there is no possible question that many so-called colleges are not above the level of city high schools, and a year of college work would not really give the prospective medical student any training superior to that which would be indicated by a well-enforced requirement of such a specified high school course as this Association has now established. The most serious difficulty, however, is that the colleges will naturally protest against being made a convenience for giving a limited amount of specified training. Although this effect was distinctly outlined in the report of the committee printed by the Council of the American Medical Association, yet the attitude of the colleges was somewhat obscured and possibly unrecognized through the manner in which the statistical results were presented. The literary institutions at both ends of the scale were alike in their statement that such work could be obtained under their auspices and would be performed to the satisfaction of the medical authorities. The reasons for approval in the two cases were, however, radically different. The stronger institutions offer larger elective courses; in many cases they have their own medical schools, and as these schools in general are turning towards higher requirements they do not hesitate to indicate that they will comply fully with conditions. On the other hand, the weaker literary institutions are exceedingly anxious to attract students, and are often over-sanguine of their ability to give such work as may be asked for.

The careful examination of the report of this committee, however, shows more distinctly that many of the Eastern colleges and also of the strong Western colleges are united in opposing any such plan, holding it to be unfair, and furthermore entirely foreign to the purposes of their foundation and the ideals they are seeking to attain. It is also true that the proposed year's work is almost exclusively in the scientific field, and hence antagonistic to the historic conception of the New England literary college where science studies are largely elective and are introduced later in the course. An additional objection was put by President Hadley of Yale in the following words: "The demand for places in our undergraduate courses is so far in excess of what we can readily meet that we can hardly arrange to take men for one year with a view to letting them leave us at the end of that time. We must, I think, arrange our courses for men who expect to stay longer." President Hadley's attitude is said to be shared by more than a dozen of the most prominent Eastern colleges.

There is no doubt that the influence of all such colleges will be exerted to hold students not merely one or two years but for the full four-year course, and any such proposed standard as this must recognize frankly that such colleges are permanent obstacles in the way of its practical realization.

The actual working out of the problem is indicated by the conditions which prevail with reference to another option that has been tried by institutions at various points. Certain university medical schools have solicited and obtained from a few literary colleges a provision which is publicly announced in their catalogue permitting any student of senior standing to take his senior year *in absentia* at an approved professional school, and on proper certification at the close of that year to receive his diploma with his class as if he had remained in residence. This provision is entirely analogous to that in vogue at several of the strongest Eastern universities where a senior student in arts and sciences is allowed to enroll as a freshman student in a professional school of the same institution and thus qualify for the fourth year of academic standing and the first year of professional training within the same period of time. In these universities the opportunity is embraced by a reasonable percentage of students who are seeking both degrees. Many of the literary colleges in the Central and Western States have most vigorously opposed the granting of such a privilege through the intensity of the opposition is often indirectly proportional to the strength of the institution. At the same time when we come to consider how the plan has worked in actual experience it must be confessed that there have been practically no results. In two widely separated conferences of college presidents representing such institutions in the Central and Western States the privilege was made the subject of discussion this past winter, and at both of them the actual experience as reported was identical. Students who have completed the junior year in a literary institution are not willing to forego the pleasures and privileges of senior standing, and despite pressure will stay in the literary college for their last year's work.

A final rather serious objection to the practical working of the plan appears to be the question of what college work should be accepted. The report of the committee speaks unequivocally in favor of insisting on high-grade work; it even goes so far as to state openly that "the preliminary college year must mean more than a year of actual work in many cases. But we believe the medical schools should stand rigidly for that, and insist on this amount of work whatever time it may take." Such a position naturally commands general approval, and yet the actual enforcement of this provision is open to the same grave abuses which led to the abolition of the time credit granted to college graduates supposably on the basis of work done. The adjudicating body is prejudiced, and there is no absolute standard to be followed.

All of this evidence seems to my mind to indicate clearly that in actual practice the single year of college preparation is not a feasible general standard for entrance to the medical schools, or rather, perhaps, let us say that if adopted it will tend more strongly than ever to emphasize the advantages of the schools possessing genuine university affiliations and to curtail radically the opportunities of the independent medical schools. Such medical faculties as are connected with State institutions or endowed universities will still announce and enforce one year of college work as a preparatory requirement, but this will be merely a preliminary step towards the introduction of two years of college work which is the natural minimum requirement in my opinion for university schools.

State Board Advanced Standards.—The advance in preliminary requirements beyond the four-year high school course has been participated in by certain State Boards. Thus Minnesota and North Dakota have established, to take effect in 1910, a requirement for preliminary education embracing two years of college work above the four-year high school course. Connecticut and South Dakota have set the standard for the same date to include one year of preliminary college work. In his presidential address last year, Dr. Kober pointed out the injustice of the isolated action by Minnesota, but there is another feature which also deserves passing mention. It may be wise for a State which is already well supplied with physicians to raise the standards of professional education beyond those obtaining in less favored commonwealths. But this policy is not so clearly justified in such a State as North or South Dakota where the number of physicians is radically less in proportion to the population than in the average of the country, and where at the same time the inhabitants are scattered over so large an area as to require a relatively greater number of physicians as compared with other States. The emoluments of a physician are naturally less in a sparsely settled community, the hardships of pioneer life add to the difficulties of the situation, and from the theoretical standpoint one would expect in natural evolution to find such new communities establishing relatively easy conditions for medical licensure, whereas in the older, more crowded commonwealths, where the organization of society is more highly perfected, and all opportunities more accessible, the natural tendency would incline towards the establishment of severer standards. This has proved true in the history of the Old World, and in almost all parts of our own country hitherto, and it would be interesting to know precisely what influences have brought about the distinctly abnormal conditions indicated. Personally I cannot see that such a movement is favorable to the elevation of medical standards. Evidently it may easily emphasize the spirit of local antagonism which, as already noted, certainly hinders real advance. For the sake of fairness it is to be hoped that the regulation will be applied to individual graduates and not to institutions. Any effort on the part of a single State to coerce honorable and self-respecting colleges is to be deplored.

Time Credit for College Graduates.—A much discussed question is that time credit in medicine for college graduates which deserves brief attention at this point. It is well known to the Association that I have always been in favor of granting proper credit to proper schools. The contention of the colleges is pedagogically unassailable that, so far as their work is of the required standard and so far as it does prepare a man specifically for the higher work of a medical course, just to that extent it should be accepted in the professional school. It is pedagogically absurd to place the college graduate with thorough training in general science subjects, such as is given even in our standard, old-style New England colleges, on the plane of the mere high school graduate. It is, however, perfectly apparent that the credit should not be a blanket allowance made to any holder of any degree, and careful examination of the possibilities has brought to light some facts which may be of interest to this audience. When discussing in detail the conditions in different States with certain members of our Association who have an unusually wide personal acquaintance with educational institutions, I found we reached practically a unanimous conclusion, namely, that within the entire range of colleges in the United States there were in all not over thirty which give scientific work of a character and with an equipment such as to justify its acceptance by a reputable medical school. These thirty institutions are variable in type in that they include some of the smaller State universities as well as denominational and privately endowed colleges. It appeared reasonably clear that they were not likely to work together on any uniform plan for the achievement of the end sought and that the majority of them were neither seeking for such credit nor apparently interested in the proposition, so that whatever might be done would affect in all probability only ten or a dozen colleges, a very small fraction of the total number in the United States.

Supposing, however, a larger number could really be interested in the proposition, one might expect, on the basis of their past history, that not over 100 to 125 of their graduates would apply each year for entrance to our medical schools. This figure is only 2 per cent. of all graduates from medical colleges last year and less than 15 per cent. of the college graduates granted medical degrees last year, as there were approximately 5,000 graduated in 1907 from the medical colleges of the United States, and among them were 903 holding other degrees.

It is of more than passing interest to note where these 903 college graduates were found. Hopkins, Harvard, and Western Reserve furnished 150, or just one-sixth of the total number, and practically all of the graduates from all of these

schools held an academic degree. Michigan, Chicago, Minnesota, Iowa, Nebraska, and California furnished 155 degree holders out of a total of 300 graduates from those schools, so that in a total of only 9 per cent. of the medical graduates of the United States the institutions named furnished 33 per cent. of the men holding other college degrees. Evidently college men will enter the profession of medicine through those institutions which are working out a pedagogical relation between the college course and the professional training, and such institutions have in the past year furnished nearly three times as many students as could be gathered from literary colleges under any probable system of coordination. This does not, in my opinion, excuse the injustice in refusing reasonable recognition to the work of high-grade literary colleges. It does show that the obstacles of various sorts which have been placed in the way of such institutions by the unthinking and unpedagogical objectors in the ranks of medical teachers are serving to force the solution of the problem along another line. Educational evolution like any other phase follows the line of least resistance or of easiest adaptibility. It is evident also that the further advance in entrance requirements will tend of itself to settle the question with regard to possible time credit for literary colleges. Meantime this Association should follow closely the results obtained in New York where under exceptionally able auspices there is being conducted by State and college authorities a most thorough investigation of the situation. The conclusions reached will assuredly possess a sound pedagogic basis, and should be utilized by this body in formulating rules of procedure for itself. In fact whenever educational authorities of standing arrive at positive findings in considering any phase of medical education, it becomes the duty of this Association to take prompt advantage of such expert opinion in revising if need be its previous policy.

Standards Within the Medical Course.—The earliest movements towards the establishment of standards for the professional training in medicine concerned the time element and found official expression in the constitutional requirements of this Association governing the minimum length of each annual session and of the entire course. Much later the content of the course was brought under discussion, and finally the report of a Committee on the Medical Curriculum led the Association to adopt the general outline of work widely known as Kober's curriculum and subsequently adopted as standard by other organizations also. This plan of medical studies has been shown to possess considerable flexibility and consequently to be adaptable to varied conditions while it serves to limit some of the abuses due to the omission of essentials or overemphasis of single branches which have been so strongly and justly criticised by various writers.

A practical advance of great importance is that which was undertaken a year ago in appointing a committee to prepare a syllabus covering the subjects in the early part of the medical curriculum. The discussion of the apportionment of time to individual subjects and of the order of the work as well as of the period to be devoted to subsidiary sections is sure to yield most valuable results, especially so since the gentlemen who have agreed to lead in the discussion are men of wide experience and unquestioned standing in their respective fields. Any conclusions which they reach will command the support of the educated world and will constitute a most valuable contribution to the subject of medical education.

The plan of dividing the examination for medical licensure, presented so admirably by Dr. Means, affords a basis for more thorough and more practical tests, for eliminating the meaningless work of quiz schools, and measuring properly the results of all medical colleges by introducing a searching inquiry into the fundamental scientific branches. It will also weed out more fairly those students who cannot meet requirements and save them time and expense, which may be profitably employed in some other field of work. The plan has proved successful in other countries under the test of time. This Association, in my opinion, should take positive action looking towards the adoption of such a method, and should seek cooperation from the American Confederation of Reciprocating, Examining, and Licensing Medical Boards in attaining this end.

Pedagogical Defects.—Permit me now to recount briefly some features in the situation which appear to be unpedagogical and unworthy of a place in medical education. Indirect effort has been undoubtedly exerted by persons singly or in organizations to adjust legislation and standards so as to favor one locality above another, or to bolster up a local institution which was inherently too weak to meet standard tests. No fair-minded man will ever support such movements publicly, and fortunately the private instances have been so insignificant as to exert comparatively little influence on the general situation.

Apart from these, however, there has been, I am convinced, in some cases far too great insistence upon minor technical detail. The educational authorities in control of medical standards in one region have introduced requirements and stipulations in detail which are difficult of realization under the educational system of another region, and each one of the agencies noted above as influencing general standards throughout the whole country have with great vigor insisted upon its own construction of certain trivial details which in no wise affect the real basis of the standards set.

A real difficulty of more serious character is the difference in the perfection of educational organization and work in different sections of our country. There is no doubt that the newest States are inferior to the oldest and there is also little question that the educational advantages in the North are more abundant and more highly developed than in many parts of the South. This renders it exceedingly difficult to adopt a plan of action which shall apply to all sections of the country.

Another element in the situation, which personally I deem to be distinctly unfortunate, is the effort to reduce all things to a statistical basis. Not only are so many of the facts stated in statistical tables of doubtful importance, but some of them are entirely incorrect, and yet these very items are cited from one end of the country to the other as evidence of perverse tendencies in medical education. A single instance will suffice to explain what I mean. Some years ago an indefatigable statistician published the

statement that at the University of Nebraska College of Medicine, 780 hours were devoted to Orthopedic Surgery. When I inquired the source of his information since this did not correspond with any at my command, he apologized, explaining that it was a stenographer's error in tabulating college reports. He courteously promised to make prompt and full public explanation of the error. I have also endeavored to run down this statistical freak, but thus far the explanation has never caught up with the original statement, and twice within the present year I have seen his stenographer's error printed in large sized type as a demonstration of the inefficiency of medical education.

But the real fault in the statistical method is of another type. Men prove from the same set of figures the clear superiority of every life insurance company which enters into the consideration. The man who is wedded to mathematics can add, subtract, multiply, and divide until he has adjusted his computations to any conclusion that he desires to reach. The conditions of any institution can be, in truth, only very imperfectly represented in statistical fashion, and the conclusions very generally drawn from such representations are often only partly true or even entirely unwarranted. This was pointed out clearly by Dr. Dodson in comments published a few years ago on the statistical tables printed in the *Journal of the American Medical Association.*

I cannot help feeling also that the statistical data thus far published deal remotely if at all with the real educational side of the question. They show absolutely nothing regarding equipment and facilities, they cannot enumerate or measure educational organizations and methods. They assign clearly overweight to a series of examinations and encourage unpedagogic methods introduced for the sole purpose of obtaining unnatural results in such tests. In one instance described before this Association last year by Dr. A. D. Bevan, they have induced a fake institution to reduce its entire education to a series of memorites exercises in cramming for examinations, and have given foundation to its widely heralded boast of securing results which surpass institutions of high character and educational worth. In another instance, a glib graduate of a cheap school has toured the country taking examinations with great success in many States and imparting to his alma mater a cosmopolitan character in the statistical summary. The advertisement was no doubt well worth the expense, and the incident indicates a new specialty in the medical field which properly cultivated will yield good results—in a statistical way.

To meet this difficulty some change of policy is necessary, and that change should be in the direction of emphasizing the character of work which the better schools are doing. We are led thus naturally to the introduction of practical features into the tests, since by means of these alone is it possible to measure the adequate use of laboratory work in the training of the candidate. I hope that it may be possible for this Association to take some definite action at this meeting recommending the introduction of practical tests into the licensure examinations and instructing its committee on cooperation with State examining boards to urge the early incorporation of such features into State examinations.

The Advertising Tendency.—The defects which have been mentioned are largely outside of the colleges themselves, but there is one to which I would call attention here which is inherent in the present organization of many institutions. It is the advertising tendency that is utterly unworthy a place in the training schools of a profession that places a ban upon the advertiser in its ranks. This tendency is manifested in many ways and was discussed at length by Dr. V. C. Vaughan in his presidential address before this Association in 1902. I fear there has been little if any change since then. The spirit is still plainly marked, and a single instance will suffice to indicate the trend of the current. So far as I know in no other educational institutions are free banquets furnished at the expense of the faculty to all the alumni who will put in an appearance on stated occasions.

The movement which has resulted in the amalgamation of many independent medical schools with universities has been in the direction of progressive evolution, and has resulted in mutual advantages. These have been so evident that other institutions looking for their own advantage only have to secure the same end by mere paper affiliations. Such mergers in name only are abundantly familiar to us all. They are essentially pretenses and will fail at the crucial moment when in the process of advancement the medical school finds real need of the support of a faculty in arts and sciences to meet further increase in entrance requirements. The presence of a University President on Commencement Days to hand over the medical diplomas will not create a University atmosphere or add to the pedagogic power of the professional faculty. Unless the medical school can become really an integral part of an institution which is potentially a university, and can gain the moral and financial support which comes with real university control, it had better retain its independence and self-respect rather than encounter the criticism and danger of a sham union.

Medical Endowment.—The greatest single difficulty in the way of progress in medical education is undoubtedly poverty. Beside it all other difficulties appear trivial. Modern medical training is expensive. Rich gifts have provided for general education and for technical schools of all classes while medicine still awaits its benefactions. The situation is tersely described by President Dabney of Cincinnati as follows: "All medical instruction given here at present is at the expense of the profession. This is no more reasonable than if we were to require the present engineers to educate the future engineers, or the present teachers to educate their successors in the schools. The education of physicians is as much a public duty as the training of teachers or engineers." "It is perfectly apparent that great scientific institutions of this modern type cannot be built and supported without endowments."

This description applies equally to all parts of our country, and President Dabney's words furnish the key to advance in medical education. Whenever and wherever adequate financial support is furnished by public or private munificence, medical institutions will be enabled to make genuine progress. One welcomes many signs of an incoming tide of benefactions in the establishment of research institutes, and in the foundation of splendid hospitals. Money for instructional purposes will come next, and with financial independence other reforms follow quickly. The

recent acquirement by Tulane University of a splendid endowment for its medical department has been promptly followed by a radical advance in standards as well as facilities which places Tulane in the forefront among Southern schools, and assures the participation of the South in the movement for the elevation of standards in medical education.

The value of such endowments is two-fold since they affect other institutions as well as the recipient of the funds; for in the struggle for existence other schools must increase their own efficiency or retire from the field. In these times of progress it will not do for any school to sit idly watching the advance of neighboring institutions. It must find the means to continue the struggle or stop work. The latter fate has come to a few schools recently and is threatening imminently even more. All the evidence at hand indicates a surplus of medical schools in our country, and all agencies join in demanding the elimination of the unfit. No action will add greater strength to the forward movement in medical education than weeding out such as cannot justify their existence.

THE ETIOLOGY OF PARALYSIS OF THE RECURRENT LARYNGEAL NERVES OF PERIPHERAL ORIGIN.*

By D. BRYSON DELAVAN, M.D.,

NEW YORK.

Reviewing the history of this subject we find that at a period centering about twenty years ago, much interest was shown in its study. Led by Prof. Hermann Krause in Europe and by the late Prof. Franklin H. Hooper in this country, excellent laboratory work was done and some important facts were demonstrated. Of the main questions at issue, however, many were unanswered, in spite of the earnest efforts of a number of well qualified investigators and of controversies which in some instances assumed the proportions of bitter feuds. Of late years not much has been advanced on the subject, and that little has not been illuminating. Possibly the difficulty of the study and the lack of success attending its investigation have discouraged progress. Possibly again, in view of the present popularity of other adjacent fields, the larynx has received less attention recently than it deserves.

The serious nature of recurrent paralysis and the not inconsiderable number of patients affected by it should certainly stimulate us to more earnest effort towards the better understanding and explanation of the causes which bring it about.

In many varieties of the affection the cause is clear. In others it is obscure, as witness the number of cases in which the diagnosis has either not been made or has been clouded by conflicting opinions as to the actual effect of the supposed cause. I shall be able to do little more than call attention to some of the questions which the subject suggests and ask you to interest yourselves in taking up their investigation. Indeed, in spite of all that has been written on the subject, it may be said that the study of this department is in its infancy, for it has not even been determined whether certain toxic paralyses of the recurrents are due to central causes, to changes in the nerve elements themselves, or to neuritis from severe surface irritation.

Recurrent paralysis may be either unilateral or bilateral, and only the posterior fibers of the nerve may be involved, as in abductor paralysis, or, the paralysis may be complete.

Shurly[1] quotes Avellis to the effect that of 150 cases, the cause was discovered in only 85. Of the above 150 cases plus 19 collected by Sendziak[2] 113 were males and 50 were females. In the same series of cases, the paralysis was found 46 times on the right side, 92 times on the left side, and 12 times on both sides. In 41 cases of Sendziak, 5 were right, 15 left, and 21 bilateral. Unfortunately little reliability can be based upon these statistics. Three points become evident from them, however, as has been suggested by Lermoyez, namely,

The preponderance of peripheral paralysis over that caused by central lesions; the excess of cases in which the paralysis has been on the left side, and, finally, the greater liability of recurrent paralysis among men.

As to age, of 19 cases, 15 occurred between the 20th and 60th years. The youngest was a child of two years, the eldest was 59.

Sendziak claims to have collected 1,017 cases, which he has classified according to the form of the paralysis, as follows:

1. Abductor paralysis, 520; 2. Paralysis of recurrent, 491; total, 1,017. 1. (*a*) Unilateral abductor paralysis, 283; (*b*) Bilateral abductor paralysis, 243; total, 526. 2. (*a*) Unilateral recurrent paralysis, 397; (*b*) Bilateral recurrent paralysis, 94; total, 491.

Among the earliest observations noted with regard to them was the fact that if the recurrents were injured, dyspnea was a prompt result. This was made apparent through the effect upon them of wounds of the throat and neck. Later on the possibility of paralysis from pressure was recognized.

Finally, within recent years, a few observers have called attention to the occurrence of paralysis from toxic causes. Many cases have been reported in which the movements of the larynx have been affected by peculiar conditions of the blood due to disease or to the ingestion into the system of certain well-known poisons. Thus gradually it has become apparent that paralysis of the recurrents of peripheral origin may be due to many causes.

The consideration of paralysis due to traumatism and to pressure are very interesting topics. Moreover the subjects are far from having been exhausted. Many things remain to be explained regarding both of them.

Paralysis due to toxic agencies, however, is a subject which has been hitherto little studied. It is replete with problems of many kinds, and these again depend upon questions of surpassing interest. Few fresher or more attractive fields could be offered to the investigator, whether physiologist, pathologist, or chemist.

In studying the reports of cases by various authors, the writer has been impressed with the belief that some of them were probably not cases of actual paralysis, but of ankylosis.[3] This is especially likely to be true in such diseases as typhoid, erysipelas and other conditions attended with severe local inflammation adjacent to the joint, or, as in rheumatism and gout, with inflammation of the joint itself.

The possible myopathic orgin of loss of motion in the larynx must also be remembered. This condition may be present in wasting diseases, muscular atrophy, rheumatism, and carcinoma.

The possibility of error in deductions based upon the statistics of reported cases of paralysis, some

*Read at the thirtieth annual meeting of the American Laryngological Association, Montreal, May 11, 1908.

of which may have been wrongly diagnosed, must therefore be taken into account.

While first asking attention to the better known departments of the subject, it is to the toxic conditions that I shall finally bespeak especial attention and interest, believing that the time has come when light should be thrown upon the obscurities which surround them and hoping that ere long more complete and definite knowledge may be secured.

The causes of recurrent laryngeal paralysis of peripheral origin as far as now known may be divided into three general groups, namely:

1. Cases due to traumatism, or laceration of the nerve trunks. 2. Cases due to mechanical pressure upon the nerve. 3. Cases due to toxic influences, either of the nature of poisons ingested into the body, or of toxemias or infections generated by disease.

As has already been said, careful distinction must be made between actual paralysis and simple loss of motion due to myopathic causes. Also, from loss of motion from ankylosis of the cricoarytenoid articulations.

Of the various causes of paralysis of the recurrents, we will first consider traumatism:

Laceration of the nerve trunk may occur in any part of its course and from a variety of accidents and the injury may be inflicted from without the larynx and trachea or from within them. The list includes incised, gunshot, and punctured wounds of the neck, self-inflicted, or accidental; injuries to the nerve made in the course of surgical operations done upon neighboring parts; foreign bodies in the larynx, trachea, or esophagus, and unsuccessful efforts made at their extraction; injury to the nerve from attempts at strangling and from blows upon the larynx.

Division of the recurrent happens occasionally in cases of cut throat. The possibility of its existence should be recognized before attempting the complete closure of such wounds, as the effects of sudden urgent dyspnea would of course be very serious.

Lefferts[4] has reported a case of paralysis of the right recurrent nerve due to a punctured wound made by the point of the blade of a pair of scissors.

The recurrents are liable to injury in operations for the removal of various tumors, especially of the thyroid gland. This is particularly true of goiter, as a number of recorded instances will attest. In view of the increasing popularity of the operative treatment of goiter this should be carefully remembered.

Operations for the removal of new growths of the neck in which the necessary dissections approach the vicinity of the recurrents may easily be attended with injury to them, as also may attempts at the extirpation of diseased lymph nodes lying near to the larynx or trachea.

The writer has seen cases of paralysis of the right side of the larynx following extensive extirpation of the cervical glands in recurrent carcinoma of the right breast.

The position usually occupied by the left recurrent behind the inferior thyroid artery renders it liable to injury during ligation of the latter.

We will now consider the subject of recurrent paralysis due to mechanical pressure.

The list of known causes includes: Diseases of glands and of lymph nodes; new growths; aneurysms; diseases of the heart; diseases of the pleura and scoliosis. Comparatively few cases of recurrent paralysis have been recorded in any country. At present reliable statistics as to the relative frequency of these causes are not to be obtained. Accuracy of statement, therefore, is impossible.

Clinical experience seems to prove that this division presents by far the largest number of the cases that come under observation. Scientifically speaking they are more interesting than the cases due to traumatism, for while some are relatively common, others are rare, and while some, fortunately as a rule the more common ones, are generally rather easy of diagnosis, there are no small number which are very difficult, so obscure in fact that a positive diagnosis with the means of examination at present available to us seems to be impossible.

Many cases hitherto obscure have of late years been made clear by the aid of the Roentgen ray. Perhaps nowhere among the varied uses of that splendid contribution to science have more brilliant successes been obtained.

We will begin with the diseases of the glands and of the lymph nodes.

That a diseased condition of the thymus gland has ever been the cause of laryngeal paralysis I have not been able to learn.

Disease of the thyroid gland, however, is a common cause, occasionally from malignant involvement but far more often from goiter.

Remembering the anatomical relations of the thyroid with the trachea it is easy to understand how the recurrents might be encroached upon by almost any swelling of that gland.

The size of the thyroid tumor seems to have little effect upon the degree to which it may endanger the recurrents. Thus a very large goiter may cause little or no dyspnea. On the other hand, one of small size may prove fatal.

The most striking instance of this which the writer has ever seen came to his notice when he was Assistant Pathologist to the New York Hospital some years ago.

A middle-aged lady of rather full habit while shopping was suddenly seized with urgent dyspnea. She was hurried to the New York Hospital, which was nearby, and within a few minutes after the onset of the attack a tracheotomy was performed. Before the cannula could be inserted, she died.

At autopsy made by Dr. George L. Peabody, the thyroid appeared to be slightly enlarged. Upon exposing it by dissection, a goitrous tumor parenchymatous in nature was found, the base of which did not measure quite four inches in diameter. It was so situated with regard to the trachea, however, that both recurrents had been pressed upon sufficiently to cause paralysis, or, as is more probable, spasm of the larynx, and asphyxia.

Disease of the tracheobronchial lymph nodes has been the cause of recurrent paralysis in a number of recorded cases. These may have become enlarged from syphilis, tuberculosis, malignant infiltration, or other infections.

In a case seen by the writer at St. Luke's Hospital, New York, a child 2½ years old suffered from urgent dyspnea requiring a prompt tracheotomy which failed to give complete relief. Death followed in a few days. The child was found to have general tuberculosis, and the cause of the dyspnea was a large lymph node pressing upon the middle section of the trachea. Great obscurity must often attend the recognition of these cases. The fact of their possibility, the presence of a condition capable of causing them, the absence of other discoverable cause, and above all the use of the *x*-ray, may all aid in arriving at the truth.

Malignant disease of the thyroid, the esophagus, the neck, and the mediastinum is a common, if not the most frequent cause of recurrent paralysis. In all of these but the esophagus it is generally due to direct pressure upon the nerve trunk. While sometimes due to direct pressure from disease of the esophagus, it may also in the latter case be caused indirectly through the extension of the disease when located in the upper part of the esophagus to the larynx or trachea so that both recurrents are surrounded by cancerous masses and thus totally paralyzed. Or the paralysis of the nerves may be direct from the pressure of degenerated cancerous glands upon them.

Sandby[5] has reported a case which has become famous for two reasons—first because as a result of esophageal carcinoma *ad*ductor paralysis was first observed. Later this disappeared and a condition of purely *ab*ductor paralysis took its place. Finally the cords assumed the cadaveric position, thus proving the complete paralysis of the nerves. A second point of great interest in this oft-quoted case is that it seems to contradict the so-called "law" of Semon as to the supposed vulnerability of the abductor filaments of the recurrent nerve.

In the minds of most practitioners, the discovery of fixation of the left side of the larynx is almost proof positive of the presence of an aortic aneurism. Very often this view is correct: In the experience of the writer with the cases that have come under his observation, aneurysm of the aorta has been the most frequent cause of left recurrent paralysis. The mechanism of this is too familiar to require special exploitation. It must be remembered that bilateral paralysis with its attendant dangers may be developed by the growth of the aneurysmal tumor in its late stages.

The position of the right recurrent with relation to the right subclavian artery is such as to render it vulnerable in case of aneurysm of that vessel. Such cases are very rare in comparison with those of left recurrent paralysis due to aortic tumor. Aneurysm of the innominate has been said to be an occasional cause.

Cases have been reported in which recurrent paralysis has been caused by various diseased conditions of the heart, especially valvular disease in the form of mitral insufficiency and of pericarditis. By the use of the term valvular disease in this connection we are probably meant to understand the effects of it in the morm of dilatation or hypertrophy, the increase in the size of the organ causing it to press upon the recurrents, as would be the case in pericarditis. Apropos of this subject, the case reported by Baumler[6] presents features of extraordinary interest.

A young man suffering from syphilis and an old mitral insufficiency lost his voice synchronously with the appearance of a pericardial exudation. Examination of the larynx showed a bilateral abductor paralysis. With beginning resorption of the exudate the voice gradually returned, at first rough and hoarse. Two weeks later it became entirely normal and remained so until his death.

From its position with regard to the apex of the right lung the right recurrent may be pressed upon under certain morbid conditions of that part.

Thus, in fibrous phthisis, such cases have been found. They have also been caused by thickening of the pleura covering the right lung apex. It is said that the same thing has been seen in the case of the left lung.

Finally, a few cases are reported in which paralysis was attributed to pneumonia, pneumothorax, and pleurisy. That the paralysis was actually due to pressure and not the result of severe peripheral inflammatory conditions, remains to be proved.

By far the most interesting group of cases which come within the scope of this article are those due to toxic influences. They are less frequently observed than those caused by traumatism or by pressure, so that opportunity to study them has not so often been given.

Moreover, the physiological and pathological processes by which they are brought about are far too little discussed and much less well understood. It is proper, therefore, that particular attention should be called to them both by reason of their pathological importance and because they offer one of the most interesting and valuable fields for original research to be found within the range of medicine.

The ingestion of certain drugs and chemicals is found to produce in some cases paralysis of the recurrent laryngeal nerves.

In like manner recurrent paralysis occasionally accompanies certain acute infectious diseases. If it be true that the poison acts directly upon the nerve-elements through some especial affinity of the one for the other, then the variety of toxics capable of so acting is remarkable, and it suggests a vulnerability of the recurrents to toxic effects which is to say the least unusual and peculiar. Other sets of nerves may be similarly acted upon, as in poisoning from lead, alcohol, or diphtheria. The number of different toxins which have been said to affect the recurrents, however, seems unusually extensive.

The list of causes of toxic paralysis of the recurrents should be divided into two groups: First, mineral and vegetable poisons; and secondly, toxins generated by acute infectious diseases. To the former belong lead, arsenic, antimony, copper, iodide of potassium, iodoform, and, it has been alleged, cyanide of potassium and phosphorus.

Recurrent paralysis due to other mineral poisons must be very rare. A few cases have been observed which seem fairly to have been due to the influence of arsenic, iodide of potassium, and iodoform.

Those referred to antimony, copper, cyanide of potassium, and phosphorus are apparently of doubtful nature.

The first case on record in which the influence of lead upon the recurrents was observed by the aid of the laryngoscope was seen by Sir Morell Mackenzie[7] in 1865. He reported a case of complete paralysis of the right side of the larynx in a young man suffering from general lead poisoning. The paralysis disappeared after two months' application of electricity.

Our fellow member Sajous[8] in 1882 reported a case of bilateral paralysis of the larynx due to lead poisoning, and Seifert follows in 1884 with three well observed cases. A few others have appeared in literature up to the present time.

The cases reported in which other minerals have been thought to produce recurrent paralysis have been so few in number as to make deductions impossible. They suggest the possibility of coincidence quite as strongly as they do that of cause and effect.

Paul Heymann[9] collected over 50 cases of mineral poisoning of the larynx. He found lead to be the most common cause. Usually the abductors were affected.

Among the vegetable poisons the following have been alluded to in the literature of the subject: Alcohol, opium, morphine, belladonna, atropine, cannabis indica, cocaine.

Among the vegetable poisons mentioned, alcohol properly heads the list. Hippocrates[10] calls attention to that form of aphonia of the drunkard which comes upon him in his cups and does not disappear when he has become sober. Several good authorities have quoted the coexistence of recurrent paralysis with alcoholism. Cases have also been reported as being due to opium and to belladonna, and it has at least been suggested that similar results may arise from cannabis indica and from cocaine.

The questions raised by the action of the drugs and minerals just described upon that always peculiar pair of nerves the recurrent laryngeals are perplexing. In what manner do they inhibit the action of these most active parts?

1. Is there any truth in the supposition that there is an elective affinity existing in these particular nerves in favor of certain drugs through the influence of which the one exercises an inhibitory effect upon the other?

2. Does the drug produce changes in the nerve tissue itself which result in the loss of its activity?

3. Is the lesion a neuritis, induced by pressure, from congestion of neighboring parts or otherwise?

4. Are the effects upon the recurrent due to central causes, the latter induced by the drug?

Turning now from the mineral and vegetable poisons which may affect the recurrents, we take up the consideration of the alleged results produced by the toxins of some of the acute infections:

These include typhoid fever, acute articular rheumatism, influenza, diphtheria, typhus fever, acute croupous pneumonia, puerperal fever, erysipelas, measles, scarlet fever, gonorrhea, serum therapy.

Of 73 cases collected by Sendziak 26 occurred in typhoid fever, 18 in acute articular rheumatism, 11 in influenza, 9 in diphtheria, 3 in typhus fever, 2 in croupous pneumonia, and 1 each in puerperal fever, erysipelas, measles, scarlet fever, gonorrhea, and the use of serum therapy.

Of the infectious diseases in which recurrent paralysis may be found typhoid fever seems decidedly the most common. The paralysis may be unilateral or bilateral. It may occur early in the course of the disease, but it generally appears towards its close, during the third or fourth week.

Osler,[11] agreeing with the generally received opinion, attributes it to a neuritis of the recurrent and states that the general activity of the toxins in a given case has more influence upon the nervous system in causing the neuritis than has the temperature. In other words, the neuritis is not so apt to be developed in a case where the temperature is running a high course as it is in one in which the typhoid intoxication is profound.

Laryngeal paralysis in a severe case of typhoid is of course an exceedingly grave complication, although in the milder cases of fever if the paralysis is unilateral it is not so dangerous.

Regarding the cause of the paralysis, the question again arises as to whether, after all, the nerve irritation is not brought about by the violent surface inflammation commonly met with in and around the larynx in this disease.

While most writers state that the paralysis of the recurrents in typhoid is generally due to neuritis, certain ones believe that the loss of motion is sometimes myopathic. Degeneration of the laryngeal muscles may take place in like manner with the degeneration of the abdominal muscles in typhoid.

Morris Schmidt[12] says that recurrent paralysis has occurred in typhoid patients suffering from complicating pleuropneumonia, glandular swelling, and muscular degeneration.

May it not be possible that some of the instances reported as being due to typhoid toxemia have after all been caused by such complicating conditions?

In typhus fever as in typhoid, recurrent paralysis may supervene. It is said to be more frequent in typhus than in typhoid; it is likely to occur at an earlier period of the disease and to be of a more serious nature.

In acute articular rheumatism recurrent paralysis has been found in all its phases: unilateral, bilateral, abductor, and complete.

Here again the causes are variously stated, neuritis and rheumatic affection of the laryngeal muscles having the preference.

Clinton Wagner and others have reported cases of gouty inflammation of the cricoarytenoid articulation with perichondritis, necrosis, abscess, and sloughing of the arytenoid cartilage. The possibility of this should also suggest the possibility of rheumatic affection of the laryngeal muscles and admit of the assumption that not every case of loss of motion in the larynx is necessarily neuropathic.

Morris Schmidt[12] says that he has not infrequently seen recurrent paralysis following influenza. Other writers have reported a few such cases. This does not seem improbable in a disease capable of affecting so profoundly the nervous system in general. Morris Schmidt[12] also calls attention to the fact that in diphtheria it is still questionable whether the resulting paralyses are due to central or to peripheral causes. In the opinion of the writer it is not necessary that fixation of the larynx following diphtheria should be due to paralysis at all, since under conditions of inflammation as violent as those often found in laryngeal diphtheria ankylosis of the cricoarytenoid might easily be produced. In several cases seen by the writer of unilateral loss of motion present many years after an attack of diphtheria this has seemed to be the true explanation. The question is rendered still more difficult, however, when we remember that following a genuine paralysis the joint may become ankylosed through disease.

Apparent paralysis of the larynx may also accompany the severe infections of the throat nondiphtheritic in type, as for example the staphylococcus and the streptococcus. It seems more probable that the loss of motion is due rather to the effects of inflammation upon the muscles and joints of the larynx, than to its effects upon the recurrents.

One case each is reported of recurrent paralysis from erysipelas, puerperal fever, scarlet fever, measles, serumtherapy, and gonorrhea. In all but the first the paralysis was unilateral.

The last-named case has been elaborately described in an extensive and scholarly article by Lazarus.[13]

With regard to toxic paralysis, some very interesting questions arise.

1. If it be true that there is such a thing as a "selective affinity" between the recurrents and a given poison, in a case of poisoning we would expect to find both recurrents affected. In point of fact mineral poisons seem almost invariably to affect but one. Again, if the toxins of infection cause paralysis by exciting a recurrent neuritis, we would expect the result to be bilateral, whereas many such cases have been unilateral. Both of these facts seem to contradict the affinity doctrine.

2. Is it possible that toxins, whether inorganic or organic, produce special structural changes in the nerve tissue itself which result in recurrent paralysis? For the answer to this question we must look to the pathologist, although it would seem that simple inflammation of the nerve would be all that was necessary to inhibit its activity.

3. Are the effects of toxics upon the recurrent due to central causes? Here again the fact that bilateral paralysis is rare and unilateral the rule would throw doubt upon the probability of an affirmative answer.

4. Is the lesion a neuritis, induced by pressure from congestion of neighboring parts or otherwise? It seems probable that in many cases it is, since this would explain the presence of recurrent paralysis from so many different varieties of causes, most of which are associated with congestive conditions of the throat, and for its occurrence in so many different forms.

It is easy to suppose that an inflammatory condition severe enough to cause a cricoarytenoid ankylosis might cause a paralysis of nerves lying as near the surface as do the recurrents.

It is impossible to escape the conviction that some of the cases of recurrent paralysis found accompanying violent inflammations of the throat have been due to the effects of superficial irritation.

Nothing is more common than to find a paralysis of the posterior arytenoideus muscle accompanying an acute laryngitis. The position of this muscle near the surface and at a part of the larynx where the inflammatory conditions are apt to be most intense, would render its nerve filaments peculiarly liable to irritation and injury.

Percy Kidd[14] reported a case of bilateral paralysis of the larynx, cadaveric position, following a severe laryngitis, lasting about three weeks and ending in recovery.

Such cases are not unique. If they suggest anything, it is that surface irritation may be the cause of recurrent paralysis. In many of the diseases in which recurrent paralysis is reported to have occurred, inflammation of the throat is a marked symptom.

If it can be caused by the irritation of a simple laryngitis, it is certainly possible that the still more violent inflammation accompanying severe acute infections may produce it. Doubtless among both groups of toxic causes there are some which act in this way.

These are some of the questions that remain to be explained and finally answered. If my presentation of them has been imperfect and my deductions inadequate it must be remembered that they have thus far baffled the efforts of all who have attempted their solution. With the advance of knowledge of the nervous system in general and with the increased accumulation of clinical material it is to be hoped that better progress may ere long be made.

A study of the literature of this subject shows that it leaves much to be desired. Considering the large variety of conditions which may cause it and the vast number of the cases which many of these conditions create, as for instance traumatism, tumors, cardiac diseases, tuberculosis, typhoid, diphtheria, influenza, etc., it is strange that relatively so few recurrent paralyses have been recorded. Doubtless more careful observation aided by laryngoscopic examination would demonstrate many additional ones. Here as is the case in many other departments, many of the histories have been too incompletely recorded to be of any value.

The latest writer, Sendziak,[2] claims to have found 1,017 cases, 201 of which he says are his own. Where he found them he does not state. Unfortunately he does not give the references to them so that his statistics cannot be verified nor can the articles from which he derived his material be studied. His own articles being published in the Polish language and in obscure provincial journals makes them almost impossible of access.

The article of Lermoyez is classic and well worthy of study. Paul Heymann's[9] monograph on recurrent paralysis due to the effect of poisons is excellent. It contains a full and very valuable bibliography.

THE OPHTHALMO-REACTION TO TUBERCULIN.

TESTS IN 321 CASES, INCLUDING 250 TUBERCULOUS.

By CAPT. CHAS. N. BARNEY, M.D.,

AND

CAPT. ROGER BROOKE, Jr., M.D.,

MEDICAL CORPS, U. S. ARMY.

The tests upon which this article is based were made by us at the U. S. Army General Hospital, Fort Bayard, N. M., with the permission of the commanding officer, Major G. E. Bushnell, Medical Corps.

Conditions of the Investigation.—Owing to the large amount of material presented by this sanatorium and hospital for tuberculous soldiers and beneficiaries of the U. S. Soldiers' Home, we are able to report a much larger series of tuberculous cases than anyone has heretofore reported, so far as we have been able to ascertain. We also have had the advantage of not being obliged to rely upon city hospital and dispensary cases who are under observation for short periods or at long intervals, but have had at our disposal minute records beginning at the very first appearance of the disease, including not only monthly physical and microscopical examinations and daily measurements of temperature, but also clinical histories from the first days the patients came to the attention of their medical officers in post or in the field. After a soldier who is sent here for treatment has been here for six months, he is either returned to duty, retained for further treatment with a view to subsequent return to duty, or discharged and readmitted as a beneficiary of the Soldiers' Home. Persons in the last category are permitted to come and go at will, except that if they leave they must stay away at least three months. The result is we have clinical histories of many cases who have become

well enough to work and have gone away in the summer and come back in the winter for years.

The sputum of cases of pulmonary tuberculosis is examined as soon as possible after the arrival of the patient, and the examination is repeated every day until a positive result has been obtained or until ten examinations have been made. Sputum examinations are made ten times every month in negative cases. When a positive result has been obtained the examination is thereafter repeated only every three months.

The nontuberculous cases also are soldiers, mostly members of the Hospital Corps, and all of them have been under the observation of medical officers ever since enlistment.

Only one of the cases we report had ever received tuberculin in any form. His case is noted later.

We began this work in December, and finished it in March, but we have been carfeul to register the condition of the patients at the time of the test. We have not retouched our statistics to fit theories.

Our test solution was prepared from tuberculin furnished by the Bureau of Animal Industry of the U. S. Department of Agriculture for hypodermic tests in cattle and for experimental purposes. This tuberculin differs from Koch's old tuberculin principally in that it is not concentrated to one-tenth of its volume. It is made as follows: To bouillon prepared in the classical way, except that one-half per cent. acid potassium phosphate is used in place of salt, and neutralized with sodium hydrate to acid plus one, seven per cent. of glycerin is added. A six weeks old culture of tubercle bacilli from human sources in this medium is boiled for an hour and a half, filtered through paper, evaporated to three-tenths of its volume, and refiltered. Two-tenths of glycerin and five-tenths of a one and one-half per cent. carbolic acid solution are then added, and bring the liquid up to its original volume.

The test solution for use in the eye was prepared by precipitating the tuberculin with a large excess of ninety-five per cent. alcohol, washing the precipitate with absolute alcohol, then with ether, and drying over a spirit lamp. A one per cent. and a one-half per cent. solution by weight of the dry precipitate in sterile normal salt solution were then made, put into sterile bottles each holding from 2 to 10 c.c., and the whole put into an Arnold steam sterilizer for one hour.

We are indebted to Dr. C. A. Treuholtz, Contract Surgeon, U. S. A., in charge of the Pathological Laboratory, for the preparation of the precipitate and the solutions.

Strict precautions were taken to prevent bacterial contamination of the test solution on opening the bottles and on introducing the dropper. The solution was kept in a refrigerator and the particular bottle of solution in use was resterilized at intervals of from three to seven days, according to the frequency with which it was opened. One bottle of solution was in use for a month, and was sterilized several times without any apparent alteration in its properties.

A pipette prepared by the mercury method to give a measured drop proved so fragile and inconvenient that it was discarded. We then tried the medicine dropper with the inner tube described by Baldwin, but found that also inconvenient. So we drew out the tips of various tubes to varying calibers, put rubbers from medicine droppers on them, and used the tube which gave 200 drops in filling a graduated tube to the 5 c.c. mark. Each drop was then taken to be 25 milligrams. The drop given by the average medicine dropper is about 60 milligrams, but there is wide variation between droppers. Most observers have failed to report the size of the drops they used, even though they state the strength of their test solutions, and consequently their results are hardly susceptible of comparison. If too large a drop is used varying amounts of test solution are forced out on the cheek, even if the lids are held open, and consequently the amounts utilized are less uniform.

As it seemed probable that different tuberculins vary in strength, and we wished to avoid severe reactions, we first used one-fourth of the dose which had been employed in France. Thus, instead of one half milligram of precipitate in solution, we used one-eighth of a milligram, or twenty-five milligrams of a one-half per cent. solution. Out of fourteen slightly active, arrested, apparently cured, suspected and nonsuspected cases tested with this dose we got no conclusive reactions, though we had several doubtful ones. These fourteen tests with one-eighth of a milligram are not included in our summaries. We then increased the dose to one-fourth of a milligram by using the same sized drop with a one per cent. solution, one-half the dose which had been employed in France, and as we got on the very first day with this dose in a suspected case a fairly severe reaction, we did not further increase the dose. A twenty-five-milligram drop of a one per cent. solution of precipitated tuberculin was employed in all the cases we report.

The patient's head was thrown back, the lids held open, the test liquid dropped on the eyeball and permitted to distribute itself over the conjunctival sac before the lids were allowed to close. In order to avoid contamination of the test liquid the tube of the dropper, if it touched anything, was resterilized before being dipped again into the liquid. During the first applications of the test a few cases occurred in which the patient's lids closed immediately and threw the drop out on the cheek, and in a few cases the lids were held open too long and the flow of tears became so rapid as to fill the conjunctival sac and wash the solution out on the cheek when the lids were closed. These cases were noted, and if reaction did not occur, were tested in the other eye at a later period. For fear of the dangers of anaphylaxis we did not retest the same eye in any case. We tested no case of pronounced conjunctivitis, but did test many with mild conjunctival congestion. If one eye alone was congested we put the test solution into the other eye.

The cases tested were examined twice a day, early in the morning and late in the afternoon. We counted no case as having reacted which did not show either swelling or redness.

Results.—Most of the men instilled at 3 P.M. began to notice slight burning and smarting at the inner canthus by bedtime, six hours later, slept well, noticed some gumming of the lids on the morning of the second day, eighteen hours after the instillation, and showed redness and slight swelling of the conjunctiva, most noticeable at and in some cases limited to the semilunar fold and caruncle, with increased secretion.

Symptoms and signs increased during that day, and a few more cases showed reaction that evening. By the morning of the third day, forty-

two hours after the instillation, the reaction in many cases was beginning to disappear. Most reactions had disappeared by the morning of the fourth, but a few of the patients with the more severe reactions still had much injection and watery secretion, but were improving. About half the cases were tested in the morning, and watched throughout the day to detect early fleeting reactions. No reaction appeared later than thirty-six hours after the instillation. No undoubted reaction disappeared within twenty-four hours after the instillation. Some disappeared between thirty-six and forty-eight hours; most had practically disappeared within fifty-six hours after the instillation, or forty-eight hours after the beginning of the reaction: a few lasted three days, and no reaction lasted longer than four days. Subjective symptoms were never severe, but were sometimes absent. Most constant were a gummy feeling, a feeling as of a foreign body, slight burning and soreness. The most constant objective signs were, in the order of their frequency, gumming, increased secretion, swelling of the semilunar fold of the conjunctiva, and redness. Redness was not invariable.

The time of appearance of the reaction did not show any relation to the severity, and neither the time of appearance nor the severity of the reaction showed any obvious relation to the severity of the pulmonary symptoms or to the physical signs. The stronger reactions were distributed throughout all groups, including the nontuberculous as well as the tuberculous, the third stage as well as the second and first, and cases with fever as well as those without. The duration of the reaction was roughly proportionate to its severity. Cases with pale, waxy conjunctivæ less frequently showed strong reactions, while cases with preexisting conjunctival congestion or with conjunctivæ liable to congestion upon slight irritation, when they reacted, seemed to show more general suffusion, though not necessarily any greater subjective symptoms or longer duration. The secretion was watery and mucous, in some cases probably serous, but in no case purulent. In two cases there was slight edema of the lids; in one case a single minute conjunctival ecchymosis, which disappeared within thirty-six hours; and in one case slight fugitive circumcorneal congestion.

We treated only enough cases to show that the phenomena of reaction can be modified and even aborted by treatment.

We have seen no bad after effects, though nearly all of our cases are still under observation. In no case could we detect any general effect.

Our detailed table of individual cases is too long to be published here, but the following summaries of our numerical results give the essential facts:

We report tests in 321 cases, of whom 250 were cases of pulmonary tuberculosis. No case has been classed as tuberculous which has not been shown unquestionably to be such by both history and physical signs. In all but twelve of them tubercle bacilli have at some time been demonstrated.

Our classification is based upon a modification of Turban's scheme adopted by the National Association for the Study and Prevention of Tuberculosis.

One hundred and ninety-one cases are classed as active. This number is larger than it would be if our cases were not subject to such close observation. Many of the cases which we have classed as active would in civil life be working, without any medical attention whatever. One hundred and eighty-five of the active cases, or 96.86 per cent., reacted to a single test. If the two cases which gave only subjective symptoms with gumming and increased secretion to the first test, and gave characteristic reactions to a second test in the other eye two months later, are classed as positive, the percentage becomes 97.90, or practically 98 per cent. Among the active cases there was no essential difference between the results in incipient, moderately advanced, and far advanced cases. There were 21 active incipient cases, and all but one of these reacted, 95.24 per cent. Of 92 active moderately advanced cases, 89 reacted to the first test, 96.74 per cent. If the two cases which reacted to the second test are classed as positive, this figure becomes 98.91, or practically 99 per cent. There were 78 active far advanced cases, and of these only 2 failed to react, that is, 97.44 per cent. gave positive reactions. Thirteen active far advanced cases died at periods varying from two to six weeks after the test; all but one of them reacted positively, and in all of them autopsy showed far advanced tuberculosis. Of 145 active unimproved cases 98.62 per cent., or 97.30 per cent. if retests are not counted, gave positive reactions; and of 46 active improved cases the percentage of positive reactions was 97.83 or 95.65.

Under the heading "inactive, but not arrested," we have placed cases in which all constitutional symptoms and the physical signs of progressive disease, including fine or localized râles, had disappeared, but had not remained absent for two months. There were 20 of these cases and 75 per cent. reacted.

The term "arrested" implies "absence of all constitutional symptoms; expectoration and bacilli may or may not be present; physical signs stationary or retrogressive; the foregoing conditions to have existed for at least two months." There were 10 arrested cases, and 40 per cent. of them reacted.

The term "apparently cured" applies to cases in which all constitutional symptoms, and expectoration with bacilli, had been absent for a period of three months, and the physical signs were those of a healed lesion. Of these there were 30, of which 23 per cent. reacted. One of the negative reactions was in a man who had reacted to the hypodermic tuberculin test about six months before. Tubercle bacilli were formerly present in his sputum.

The class of "suspects" includes cases which were probably tuberculous but in which there was some doubt, as well as cases which were probably nontuberculous but had at some time given grounds for a suspicion of tuberculosis. There were 10 suspects, and 60 per cent. of them reacted. This figure, of course, demonstrates nothing as to the value of the test. Of suspects and nonsuspects together there were 71, of which 17 per cent. reacted.

Of nonsuspects—cases in which there was no reason from the history or condition to suspect tuberculosis—6 out of 61, or 9.84 per cent., gave positive reactions. Only two nonsuspects who were sick showed reaction; both had gonorrheal buboes. A case of gonorrheal urethritis failed to react. A man who had recovered from typhoid fever, complicated by pneumonia, probably due to the typhoid bacillus, two months before, reacted strongly, but he had persistent cough with spu-

tum, pain in the chest, and later spit up a small amount of bloody sputum and was classed as a suspect.

Negative Tests in Active Cases.—Out of 191 active cases 6 failed to give undoubted reactions at the first test with one-fourth of a milligram, and of the 6, 2 reacted characteristically to retests with the same dose in the other eye two months later.

Case No. 43. Moderately advanced. Maximum temperature usually 100 degrees. Sputum positive at time of test. No reaction to second test. Three months after first test is still active, but slightly improved.

Case No. 66. Incipient. Temperature normal. Sputum invariably negative for tubercle bacilli. Diagnosis based on loss of weight, blood in sputum, and signs of activity at one apex. Became inactive the following month, then arrested. Negative to retest.

Case No. 108. Far advanced. Sputum positive at time of test. Maximum temperature usually 99.2°. Left hospital. Not retested. Two months after test was known to be still living.

Case No. 109. Moderately advanced. Maximum temperature usually 99.5°. Sputum positive at time of test. Subjective symptoms of reaction with gumming and increased secretion at first test, characteristic reaction to retest. Still active three months after first test.

Case No. 204. Moderately advanced. Temperature normal. Tubercle bacilli in sputum at time of test. Became inactive the following month. Subjective symptoms with increased secretion to first test. Retest positive.

Case No. 317. Far advanced. Aged 66. Temperature 101°. Tubercle bacilli in sputum. Not retested. Died six weeks after test.

Retests.—In addition to Cases 43, 66, 109, and 204, described above, the following case failed to give a characteristic reaction to one-fourth milligram, and was retested in the other eye with the same dose two months later.

Case No. 272. Probably not tuberculous. Sputum negative. Suspect on account of slight cough, persistent temperature with daily maximum from 99° to 101°, and loss of weight. Most pronounced symptom is myalgia. Retest negative.

The following cases, negative to one-eighth of a milligram, were retested with one-fourth of a milligram in the other eye after two months.

Cases No. 169, 268, 280, 284, and 285. Nonsuspects. Negative to both tests.

Case No. 197. Nonsuspect. No symptoms of reaction to one-eighth of a milligram, positive to one-fourth.

Cases No. 199 and 247. Nonsuspects. Subjective symptoms with gumming and increased secretion after test with one-eighth of a milligram. Characteristic reaction to test with one-fourth.

Cases No. 187 and 267. Apparently cured. Negative to both tests.

Tests with Filtered Tuberculin.—Five active cases, four of them moderately advanced, and one far advanced, were tested with a test solution which had been passed through the porcelain tube of a Chamberland filter, and, in order to avoid the possible error of changing strength by filtration, had been reprecipitated and redissolved. All of these cases reacted, and in precisely the same way as cases tested with the unfiltered solution. No severe and no slight reactions occurred in any of these cases.

Discussion and Conclusions.—In view of the satisfactory nature of the results we have obtained, we must conclude that our tuberculin, our dosage, our precautions to prevent bacterial infection, and our method of administration were satisfactory.

When used with the same dosage and with the same precautions which we have described, the test is without danger to sound eyes. The bad results reported by others are very rare, considering the great number of tests which are being made all over the world, and are usually, if not always, referable to failure to observe one or more of the precautions which we have noted in speaking of the conditions of our investigation.

Mackay,[1] for example, has just reported a case of conjunctivitis lasting ten weeks after the instillation of an unmeasured drop of Calmette's 1 per cent. solution of tuberculin. This dose is about twice as large as our measured drop. What precautions were taken to prevent infection during or after the installation are not stated. No treatment other than boric acid appears to have been applied until six weeks after the test.

Our retests in the other eye after a lapse of two months make Roseneau's[2] fear that anaphylaxis would occur in the other eye appear groundless. And quite to the contrary they show the importance of retesting in the other eye cases which have given doubtful reactions to the first test. They also seem to indicate that subjective symptoms with gumming or increased secretion are evidence of reaction. If anaphylaxis to tuberculin occurs only in tuberculous cases, reactions to second tests should be counted in our summaries.

The discrepancies between our numerical results and those of some other observers are to a certain extent only apparent, since we have not lumped all our tuberculous cases into one group or at most classified them into first, second, and third stage cases, but have further distinguished between active cases, cases inactive but not yet arrested, arrested cases, and cases apparently cured.

In general our results in the three stages agree more closely with the results obtained by Calmette[3] and his followers than with those obtained by Wolff-Eisner.[4] The latter got only 70 per cent. of positive reactions in the first stage, 57 per cent. in the second, and 28 per cent. in the third stage. We attribute this discrepancy between our numerical results and those of Wolff-Eisner not only to his small number of tuberculous cases (64), and his failure to distinguish between active and inactive cases, but also very largely to the fact that he used a simple 1 to 100 dilution of old tuberculin instead of a 1 per cent. solution of precipitate. It is obvious that his test solution must be invariably weaker than ours. Eisen[5] and others have shown that many tuberculous cases which do not react to a 1 per cent. solution of old tuberculin do to a 2, 3, or 4 per cent. solution. Further, as different brews of tuberculin are of slightly different strengths, solutions of precipitated tuberculin give results which are more uniform and more susceptible of comparison than do simple dilutions of tuberculin. It is not unlikely that test solutions filtered through porcelain, reprecipitated and redissolved, as was the one we used in five of our cases, would be still more uniform in action. We consider the use of a measured drop essential to the securing of uniform results.

Negative reactions in tuberculous cases cannot be attributed to fever. Wolff-Eisner, who got only 5 reactions in his 18 third-stage cases, believes that reaction depends upon resistance and that lack of reaction is an ominous sign. While all of his 13 cases which died within six weeks after the test failed to react, all but one of our 13 cases which died within the same period reacted. It is true that our patients here live under conditions which greatly favor resistance, but such a great difference as this must be due to difference in the test solutions.

Our percentage of positive reactions in nonsuspects is smaller than it would have been if we had relied upon dispensary and city hospital cases who are not as well nourished and are not subject to such close observation during such long periods as are soldiers. Closer scrutiny of the cases classed as healthy by most observers would undoubtedly throw many into the tuberculous and suspect classes.

In connection with the cases of gonorrheal bubo it is interesting that Serafini[6] has noted the occurrence of the reaction in patients with gonorrheal joints. It is to be expected, judging from our results in nonsuspects, that at least 10 per cent. of persons with gonorrheal joints would react to tuberculin, but we have no reason to believe that the reaction would be due to gonorrhea and not to latent tuberculosis.

Specificity of the Reaction.—Our 17 per cent. of reactions in suspects and nonsuspects, together with our 10 per cent. in nonsuspects alone, agrees fairly closely with the 15 per cent. of positive reactions to the hypodermic injection of 10 milligram doses of tuberculin in 20 apparently nontuberculous cases in hospital and dispensary practice reported by one of us[7] ten years ago; and the explanation given in that report to account for reactions in healthy persons applies equally well to ophthalmo-reactions in nonsuspects. "That 15 per cent.* of patients in whom tuberculosis is not supposed to exist react to tuberculin is not an argument of much weight against the accuracy of the test, as it is well known that healed or quiescent tubercular foci are found in an enormous proportion of autopsies. Many have tuberculosis without suspecting its existence, and many get over it without having had any symptoms from it."

It is generally conceded that the Widal test for typhoid fever is specific, though it is positive in a considerable percentage of healthy people and in only about 92 per cent. of typhoid cases, and these percentages vary with the dilutions used. Whether the occurrence of reaction in healthy people with the dilution generally used is dependent upon the persistence of typhoid bacilli in the gall-bladder or elsewhere in the body, or whether it depends upon acquired resistance which outlasts the bacilli, is still undecided. And likewise with the ophthalmo-tuberculin test it is conceivable that the occurrence of reaction in healthy people is dependent either upon the existence of tubercle bacilli in old and quiescent foci or upon resistance acquired through previous tuberculosis.

The fact that we got 98 per cent. of reactions in active cases, only 23 per cent. in apparently cured cases, and 10 per cent. in nonsuspects, seems to indicate that reaction is dependent upon the existence of tubercle poison (under natural conditions bacilli) in the body. Failure to find gross or even microscopic lesions at autopsy does not rule out the possibility of the existence of a small lesion unless the autopsy is more thorough than is usually practicable. The more experience we have with the ophthalmo-reaction the more we are inclined to believe that under the conditions of our test the reaction does not occur without the existence of active or clinically inactive tuberculosis.

Nature and Prognostic Value of the Reaction.—The nature of the tubercle poison, of its action, and of the processes involved in immunity and hypersusceptibility to it are so little understood that no theory yet advanced to explain the phenomena of the ophthalmo-reaction is quite satisfactory.

Wassermann considers the tuberculin reactions to be due to the combination of soluble toxin contained in the test solution with an antitoxin.

Wolff-Eisner has elaborated the theory that they are due to the action on the body of an endotoxin which is set free by lysis of bacilli existing in the test solution by a lytic material present in tuberculous cases, and that the action of this poison set free by bacteriolysis varies according to the patient's condition as to hypersusceptibility or resistance induced by repeated doses of the tubercle poison. In order to explain reactions with tuberculin which has been filtered through porcelain he further assumes the existence of ultramicroscopic fragments or spores of bacilli in the filtrate.

He concludes from the results of his tests that the local reactions to tuberculin are a measure of the ability of the body to resist, but his results differ markedly from ours and from those of the French, and we attribute his low percentage of reactions in tuberculous cases to his use of a 1 per cent. dilution of tuberculin instead of a 1 per cent. solution of tuberculin precipitate.

It is quite probable that the reaction is dependent to a certain extent upon the presence of some degree of actual resistance, and if we used a much weaker test solution it is not inconceivable that we might detect the prognostic value which Wolff-Eisner attributes to his test; but our results with a stronger test solution make it inconceivable that the reaction to our test is a measure of the *extent of ability* to resist, unless we assume that the 12 of our patients who reacted out of the 13 who died of tuberculosis within from two to six weeks, *i.e.* 93 per cent., were better able to resist than were those patients, only 23 per cent. of whom reacted, who had shown their ability to resist by becoming apparently cured.

Let us put our numerical results in the form of a table of summaries.

Tuberculous cases.	Active	97 to 98 per cent.
	Inactive, but not arrested	75 "
	Arrested	40 "
	Apparently cured	23 "
Suspects and nonsuspects		17 "
Nonsuspects		10 "

It becomes obvious that, with the dosage we employ, the occurrence of reaction depends upon the amount of poison the patient is receiving from his lesion, rather than upon the extent of his ability to resist.

For the purpose of explaining the unusual as well as the usual cases, we assume that there is some ability to resist in practically all persons, until perhaps a few hours before death, and sug-

*The sentence quoted says 18 per cent., but reference to the rest of the article shows that to be a misprint for 15 per cent. Of 20 healthy cases 3 reacted.

gest the hypothesis that reaction—at least to our dosage—occurs only when in addition to resistance, natural or acquired, there is absorption of tubercle poison, either from a tuberculous lesion or by artificial introduction into the body. Our experience seems to indicate that variations from the usual course of reaction depend upon local conditions in the conjunctiva, such as the condition of the absorptive channels and the amount of secretion diluting the test solution, rather than upon variations in resistance of the body to the bacterial poison; that the severity of reactions also is largely controlled by these local conditions; but that in some measure the severity of the reactions, and as a general rule the occurrence or nonoccurrence of reaction, are not dependent upon local conditions. Excepting negative reactions due to faults in technique, and variations in severity due either to faults in technique or to local conditions in the conjunctiva, negative or slight reaction to our test dose would indicate, according to our hypothesis, either slight poisoning or slight resistance, and strong reaction would indicate either strong poisoning or strong resistance. We attribute no prognostic value to the test, except that with minute lesions which can be expected to give off but little poison, our hypothesis would interpret strong reactions as indicating strong resistance, and that in patients who have shown their ability to resist by becoming apparently cured, absence of reaction would indicate little or no absorption of poison. Our hypothesis explains lack of reaction in active cases, when not due to faults in technique, on the same ground as it explains weak reactions in these cases, not as meaning necessarily lack of poison or lack of resistance, but only slight poisoning or slight resistance, since with a stronger test solution many of these cases would react.

Diagnostic Value.—As the dosage which can be safely employed is limited by the severity of the reactions obtained it is not advisable as a general rule to increase the dose beyond one-fourth of a milligram of precipitated tuberculin in solution, and consequently we cannot expect to get more than 97 or 98 per cent. of positive reactions in a series of cases of active tuberculosis. And until the conditions under which anaphylaxis occur are better understood it is just as well not to retest with a larger dose active tuberculous cases which have failed to react to one-fourth of a milligram.

In general, we should say that the diagnostic value of the ophthalmo-reaction is as great as that of the Widal test for typhoid fever. The reaction to one-fourth of a milligram is more certain to be obtained in active cases of tuberculosis than are bacilli; but in every patient in whom reaction is present the conclusion must not necessarily be drawn that the symptoms of the disease from which he is suffering are due to tuberculosis.

The greatest practical value of the test is of course in assisting in the diagnosis of the tuberculous basis of slight signs at one apex when bacilli are not present in the sputum, and in the diagnosis of tuberculosis localized outside of the lungs.

If no reaction is obtained to a properly given dose of one-fourth of a milligram in an individual the chances are ninety-seven out of a hundred that he has no active tuberculosis.

If reaction to this dose occurs in an apparently healthy person the probabilities are that he has a small focus of tuberculosis, either active or clinically inactive, together with strong resistance; but as this has not been unequivocally demonstrated, and as the lesion, even if it does exist, may never give symptoms, it is not wise in practice to assume that the occurrence of reaction invariably denotes the existence of tuberculosis. The occurrence of reaction in an apparently healthy person should, however, put the physician on the watch to detect the earliest symptoms of tuberculosis in case any should appear.

The test would be of value as a rough test in large numbers of people, as in recruits, but the presence of reaction should only lead to more careful examination and not in itself be taken as certainly indicating clinically active tuberculosis.

NOTE ON DEUTSCHMANN'S SERUM AGAINST INFECTIOUS DISEASES.

By EUGENE CARAVIA, M.D.,

NEW YORK.

Professor R. Deutschmann of Göttingen (now of Hamburg) in his endeavors to evolve a preparation against infectious conditions of the eye, noticed that if horses were fed with increasing doses of sterile yeast for a definite length of time, they acquired a greater power of resistance against microbic infections. With the object of utilizing this fact in the treatment of infectious diseases, Dr. Deutschmann was led to draw from the blood of animals thus treated a serum, according to the usual technique.

Thus far the results obtained have encouraged him and others, who have been using the serum for the last year or so, in the belief that a valuable weapon has been added to the armamentarium of physicians and surgeons in their combat against local or constitutional infectious diseases.

Deutschmann's serum is not a bactericide or an antitoxin; it is a polyvalent serum neutralizing germs of all kinds; not germs of one kind only. Its action is due to the introduction into the circulation of yeast-fed animals of an as yet unknown substance, which seems to be an ultimate result of a series of chemical reactions set up in their digestive apparatus. As long as the animal's health is normal, this unknown substance remains in the circulation unchanged and unutilized. If, however, the animal is exposed to a bacterial infection, the cells of the yeast-fed animals will take up this unknown chemical substance, which, by imparting new energy, increases their resistance to the bacterial invasion of the organism. The same action takes place if a serum from yeast-fed animals is injected into a patient suffering from microbic infection. The strengthening of the cells and their increased resistance put the infected body on the same plane as that of a healthy one, able to defend itself against invading microorganisms.

Deutschmann first employed his serum in a large number of traumatic or postoperative infections of the eye. But soon other German practitioners used his serum in cases of infection with staphylococci, streptococci, pneumococci, or their toxins, and it not

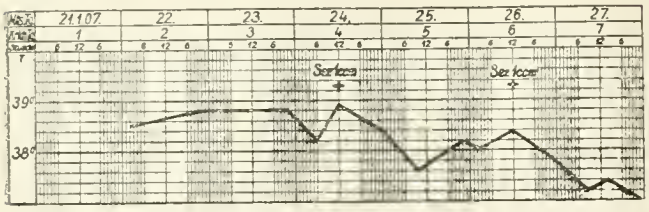

Chart 1.—Pneumonia of the left lower lobe in a woman 67 years old with diabetes; recovery.

only exerted a very favorable influence upon the patient's general condition, but also shortened the progress of the disease itself.

In apyretic conditions, the injection of 1.5 to 2 c.c. of serum has no influence on the temperature. In acute infectious febrile affections the temperature falls gradually but continuously, and in six to twelve hours reaches the lowest point. At other times, in the first two or three hours after the injection the temperature rises somewhat, to fall two or three hours later. In some instances there is a less decided drop in the temperature; it rises again the day following the injection, to fall the third day without another injection; and this fall remains, when the case is to terminate favorably. The frequency of the pulse is moderated, becoming regular, fuller, and stronger. Veterinary surgeons (Dr. Wolf of Cleve, Germany) have noticed in animals an increased secretion of urine and a manifestation of well being.

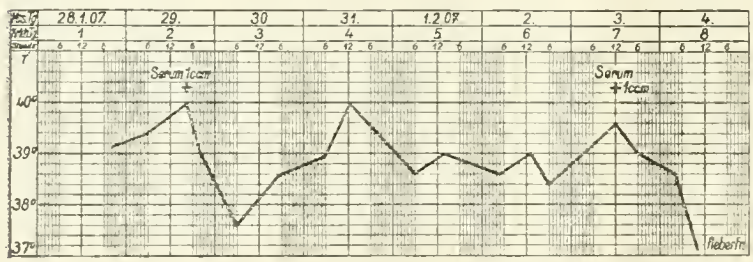

Chart 2.—Pneumonia of the left upper and lower lobes in a man, 27 years old; recovery. A fall in the temperature, with sweating, occurred after the first injection; the return of fever occurred with the invasion of the upper lobe.

The serum is well borne, not causing any harmful symptoms other than itching, erythema, or urticaria, similar to what is observed whenever a serum is employed for some time. This so-called serum affection is, however, not so frequent in the use of the Deutschmann serum.

The dose varies, according to the age of the patient and severity of the infection, from 0.75 to 1 c.c. in young people, to from 2 to 4 c.c. in adults. The initial dose should be the larger one. One, or at the maximum, two days later, the injection in smaller doses must be repeated if there is not a critical fall in temperature.

In chronic cases one injection of 0.5 to 4 c.c. is given, and if necessary repeated, according to the results obtained, two or three times a week, provided no special idiosyncrasy against the serum exists. In such cases treatment must be stopped, to be started again a few days later. The injection is usually given into the cellular tissue. When injected into the muscular tissues preference should be given to the pectoral or abdominal muscles. The serum may be given per rectum instead of subcutaneously. As the small amount of liquid used may be retained in ordinary syringes, Prof. Deutschmann advises the attachment to a Pravaz syringe of an olive-pointed capillary catheter, for the rectal injection; in such cases the dose must be doubled.

In acute and chronic purulent inflammations of the eye of microbic origin, Deutschmann's serum renders much valuable service. I cite herewith a few cases to demonstrate its value. For more

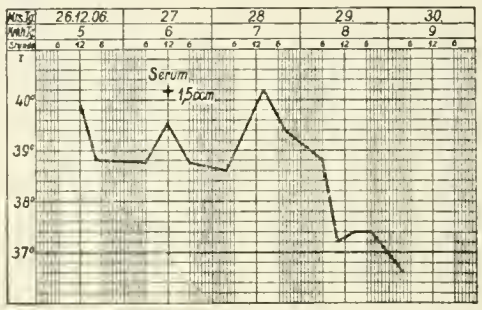

Chart 3.—Pneumonia of the right upper lobe in a patient, 34 years old; recovery.

detailed history I would refer to Deutschmann's article in *Beiträge zur Angenheilkunde* for August, 1907.

Case I.—Thos. L., 7 years of age. On August 26, 1906, received a pen wound in the right eye with corneal perforation and prolapse of the iris. Lens and vitreous affected. Clear vision five-eighths; next day severe infection. Eyeball enlarged and inflamed. Anterior chamber full of pus which also covered the iris. The prolapsed iris was removed. As tentative treatment on the second day I injected 1 c.c. of serum for preservation of the eye of which we had contemplated the enucleation. The inflammation receded gradually, and two months later the eye appeared opaque but without irritation. After iridectomy patient was able to count fingers at five feet and improvement still continued. No other treatment than the injection of the special serum was given, the eye being kept under a light bandage.

A series of difficult cases of so-called hypopyon-keratitis healed rapidly with very slight corneal opacity. Deutschmann cauterizes without exception all ulcers with the Paquelin or the galvanocautery,

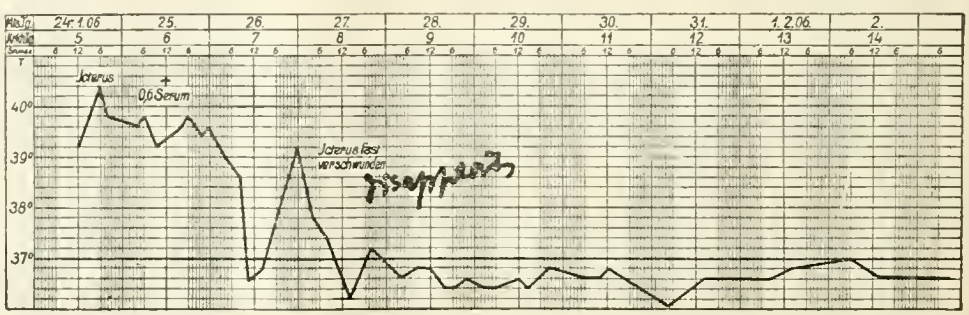

Chart 4.—Pneumonia of the right upper lobe in a 6-year-old boy; recovery.

and if on the next day no improvement follows, he applies his serum.

Case II.—Mr. H., 54 years old. Severe repeated alternating iritis of unknown cause, probably of arthritico-rheumatic origin. For years he was treated with inunctions, iodides, and salicylates at periods of several months at a time. The last attack was in the spring, and it was not until fall, after uninterrupted treatment, that there was some improvement; and then only for a short time. Then inflammation began anew with violent injection, pain, diffused aqueous humor, and opacity of vitreous body. He was now treated only with Deutschmann's serum, warm poultices when pain was severe, and a few drops of weak atropine solution. All symptoms receded and in nine weeks the patient was free from any trouble and could use the eye. Three months later there was renewed infection with pain. After two injections 1 c.c. each, the attack ceased; the eye was pale and the patient was able to resume his work.

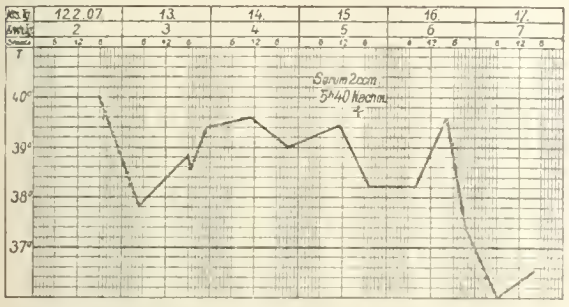

Chart 5.—Pneumonia of the right lower lobe in a patient 29 years old; recovery.

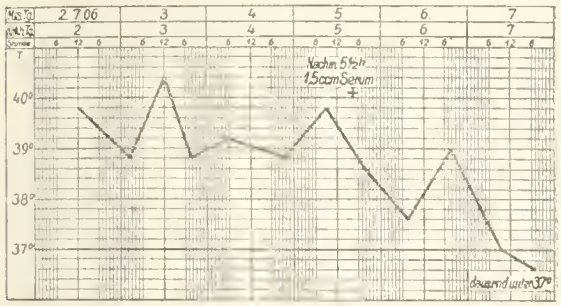

Chart 7.—Pneumonia of the middle lobe of the right lung in a patient 33 years old; recovery.

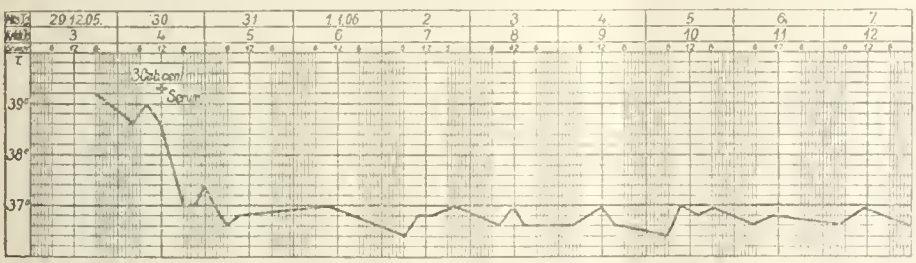

Chart 6.—Pneumonia of the left lower lobe in a woman, 22 years old; recovery.

Case III.—Mr. M., aged 42 years. Severe acute purulent iridocyclitis, thickening of the cornea, diffuse yellowish infiltration of the vitreous bodies. This was the only useful eye, the other having very weak vision. Aphakia of the now diseased eye, which had been operated upon years ago. Treatment by Deutchmann's serum, one injection of 1.5 c.c. every second day. Improvement followed the first injection, the vitreous body became clearer. Three weeks later the eye was healthy with full power of vision, as before.

Case IV.—Miss H., 25 years old. Burns from hot grease in left eye. Usual treatment brings no relief. The eye was greatly inflamed and painful, there were three small foci of central corneal infiltration, and a spot in the ciliary body lightly blue as in episcleritis. Cauterization, instillation of cocaine with novocaine and adrenalin. No improvement. A second cauterization was also without success, and was followed by increased inflammation. An injection of 0.75 c.c. brought a decided change. With the second injection the pain disappeared. The serum injections were continued every second or third day, and healing with comparatively slight corneal opacity took place in three weeks.

Case V.—Miss K., aged 16. Left eye old corneal opacities with fresh pannus, marginal phlyctenula and infiltration; ptosis. Treated for several months by other physicians without the slightest benefit. The patient was scrofulous and had an eruption under the arms and on the breast which was very refractory to treatment by ointments. An injection of 1 c.c. serum was given two or three times weekly. A remarkable improvement followed with healing of both eye and skin affections and improved general condition.

Case VI.—Miss U., 64 years old. Diabetic. Mature cataract. Extraction without iridectomy. Progress was good the first three days, but on the fourth day the patient was restless and the wound was reopened. The anterior chamber was turbid, some deposit on iris. An injection was given of 1 c.c. of serum. Next day the anterior chamber was clearer, and the iris was free from deposits. Another injection was followed by complete clearing and irreproachable healing.

At the Allegemeine Krankenhaus of St. George, Hamburg, Drs. Deneke and Zeckendorf have employed the serum in twenty-four cases of croupous pneumonia. Three of the patients who were in a critical condition when the injections were employed, died. In some cases the action of the serum was shown by the falling of the temperature and improvement in general condition. On the fourth day, and once on the second day, it was noticed, there was a sudden critical fall in the temperature with

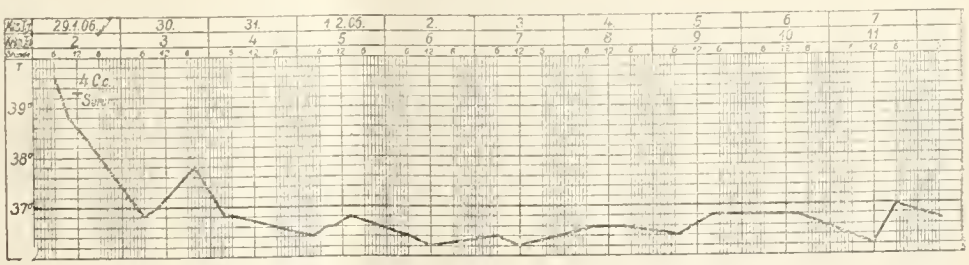

Chart 8.—Pneumonia of the left lower lobe in a lad 20 years old; recovery.

rapid recovery after the injection. In the other cases the temperature fell on the day the injections were given or on the second day, after a slight rise.

A glance on the temperature chart here appended will show that if Deutschmann's serum is not a "specific" against pneumonia, it acts like one. It takes good care of the patients without cold baths, alcohol, expectorants, or heart stimulants. There is no doubt in the minds of those who have seen the action of this serum that a timely use will greatly reduce the mortality from lobar pneumonia.

In case of acute infectious tonsillitis with strongly inflamed tonsils, painful deglutition, swollen and sensitive submaxillary glands, an injection of one c.c. of the serum brought the temperature down to normal the following day. The patient, a boy 10 years of age, was up three days after the beginning of the attack. Only a salt water gargle was employed beside the injection. Formerly, similar attacks kept the patient in bed eight days.

The writer has employed Deutschmann's serum in two cases of measles. One injection of 1.5 c.c. in each case, brought down the temperature in twelve hours and favorably influenced all other symptoms. One of the cases was in full eruption when treatment was begun. The patients felt well and hungry. Recovery was uneventful.

In a case of scarlet fever with severe initial symptoms of fever, vomiting, diarrhea, and backache, one injection of 1 c.c. serum was given. The patient, unable to be attended at home, was taken to the Willard Parker Hospital. The patient's relatives told the writer that all the annoying symptoms were stopped the very next day after the injection. Dr. Escoyez of Boussu Les Mons, Belgium, informs me in a recent letter of the success he has had in a case of scarlet fever treated with Deutschmann's serum, though without intention to draw general conclusions based on that case alone.

A case of swollen tonsils with difficulty of swallowing, pain, and a white suspicious exudation was injected with 1 c.c. Deutschmann's serum, pending the bacteriological examination of the culture taken immediately before the injection. The Board of Health reported the presence of the Klebs-Loeffler bacillus and diagnosed the case as one of diphtheria. On the strength of the report, I advised the patient to have the diphtheria antitoxin employed. I found him the third day after the injection with one tonsil perfectly normal in appearance and the other with only a very slight white patch. The temperature was normal. The patient said he felt as well as possible and wanted the antitoxin injection postponed. Nothing was heard of him for twenty-four hours, and I thought it my duty to notify the Health Department. When a physician from the department went to visit the patient (five days after the injection) he found that he had gone to work. After locating him and taking a fresh culture the Board of Health reported that no more diphtheria bacilli were to be found. (Health Department Laboratory, No. 16,705. Reports of December 31, 1907, and January 8, 1908.) No other treatment was employed. A similar case of diphtheria was reported to Professor Deutschmann by a German physician.

A case of acute swelling in the gluteal region with pain, redness, T. 102.5° F., which did not yield to various local applications, antipyretics, and incision, receded promptly after an injection of 1 c.c. serum.

Mr. D., 42, had repeated chills on Saturday, June 6, 1908. Temperature Sunday, 105° F. Pains front and back on right side of chest. First seen by writer on Monday, T. 104° F. Pulse 110. Intense pain. Very little dry coughing. No expectoration. Dullness below crest of right omoplate. Obscure breathing. No murmur or râles. Diagnosis, pneumonia. First injection of 3 c.c. of Deutschmann's serum. Delirious during following night. Next day, Tuesday, pains disappear. Patient coughs more. Characteristic brick color expectoration. T. 104° F. Pulse 100; good, full, regular. Soft murmur extending all over right lung. Crepitant râles, but very few. Second injection of 1 c.c. Wednesday patient feels better though temperature was still 104° F. in the afternoon. Local signs same. No injection. Temperature begins to fall at 8 P. M. and continues to gradually drop all day Thursday until it reaches 101° F. at 5 P. M. Third injection of 1 c.c. Friday; temperature normal. Appetite improves. Good night's rest. Little coughing. Scanty expectoration, rose color. Saturday percussion and vesicular murmur almost normal at upper three-quarters of the lung. Few crepitant râles at the lower fourth. Patient was up and out Monday, June 15.

This serum has also been used with excellent effect in a case of peritonitis, and has given good results in chronic cases of infectious skin diseases.

In conclusion, judging from the results already obtained, it can be said that in Deutschmann's serum we have a valuable therapeutic agent which is destined in the course of time to take a prominent place in the every day practice of those who object to the depressing effects of other agents.

A NEW AND EFFICIENT METHOD OF ROOM DISINFECTION.

PRELIMINARY ANNOUNCEMENT.

By W. B. McLAUGHLIN, M.D.,

NEW YORK.

In order to make clear the advantages of the method of disinfection, which I am going to describe, it is necessary to define the exact status of the art as applied to dwellings. The methods most prominently before the profession to-day are:

1. What is known as the "Maine Method," *i.e.* obtaining formaldehyde gas by mixing 300 c.c. of 40 per cent. solution of formaldehyde and 150 grams of potassium permanganate for each 1,000 cubic feet to be disinfected. The most prominent exponent of this method is the United States Public Health and Marine-Hospital Service.

2. The "Walker Method," which consists in dissolving 20 to 25 pounds of commercial aluminum sulphate in five gallons of water, adding to this mixture 15 gallons of 40 per cent. solution of formaldehyde, and liberating formaldehyde gas by mixing 8 ounces of this mixture and one pound of unslaked lime for each 1,000 cubic feet to be disinfected. The most prominent exponent of this method is the New York Health Department.

3. The "Stewart Method," which consists in thoroughly spraying the walls, furniture, and floor of the room with a 20 per cent. solution of formaldehyde gas, and then spraying the mattresses, laying one on top of the other, and then the pillows, bedding, etc. The most prominent exponent of this method is the Philadalphia Health Department.

In the first two methods (the Maine and the Walker Methods), penetration to any extent is not claimed, and it is the custom both of the Marine-Hospital Service and of the New York Health Department to disinfect articles such as bedding, clothing, etc., in the steam autoclave. But in the Stewart

Method it is claimed that the disinfection is sufficiently perfect to render steam sterilization in the autoclave unnecessary. As authority for this procedure, I was referred to an article by Dr. A. H. Stewart in *American Medicine*, Vol. X., No. 22. A careful perusal of this article, to my mind, failed to disclose evidence of penetration sufficient to warrant the abandonment of steam sterilization for those articles requiring deep penetration. The author says: "Our success with this machine in room disinfection led us at once to test the value of spraying bedclothing in the same way instead of hauling the clothing to the Municipal Hospital and running it through an autoclave. A series of tests was made in the every-day work of the disinfectors. The floor being sprayed, the mattress was then thoroughly sprayed and placed upon the floor, and the quilts, sheets, etc., were placed one on top of the other and sprayed. Our test objects, small, oblong tin boxes with lids, inclosing strips of cloth soaked in bouillon cultures of *B. coli communis, B. pyocyaneus*, and *B. subtilis*, were placed in the mass of clothing. When the lids of the boxes containing the infected test objects were opened, 500 tests showed 99.4 per cent. killed. All test objects not killed were sporulating *B. subtilis*. These results induced us to stop the autoclave disinfection of bedclothing, except in cases of smallpox. This has been done, and as a result there has been a saving of nearly $400 per month."

According to this statement, the mattresses and each article of bedding was sprayed. If this were the case, it is evident that the killing of test objects placed as described would be of no value as evidence of penetration, no assurance being given that these test objects would have been killed had penetration been required through even one thickness of blanket. If each separate article of bedding was not sprayed no data are given by which the operator would know how often to sandwich in a sprayed article. In order to determine these points, I undertook a series of experiments, but when in the midst of them was considerably disappointed to find that this work had been covered by Dr. Rosenau, and published in a bulletin of the Hygienic Laboratory of the United States Marine Hospital and Public Health Service, entitled, "Formalin in Disinfection of Baggage without Apparatus."

As my work, so far as it went, is merely confirmative of Dr. Rosenau's, I will give his conclusions. Page 33 of the above-mentioned Bulletin says: "Large quantities of formalin poured on absorbent material in the corners of, or suspended in a box, have practically no disinfecting power between layers of blankets or sheets, even after five days' exposure. The formalin neither evaporates nor liberates its formaldehyde in a closed container at ordinary temperature (18 to 25° C.) in twenty-four hours. In two to five days the fluid will evaporate, but the formaldehyde is deposited as paraform on the spot where it was poured. This method of pouring the formalin on absorbent material is, therefore, totally inapplicable in the disinfection of baggage, in a closed container. Sprinkling formalin on baggage in a trunk or box may be depended upon to kill non-spore-bearing organisms, such as typhoid and diphtheria, through three layers of blankets. The method, however, is not a reliable one unless a sufficient quantity of formalin is sprinkled in small drops uniformly over the surface and between many layers. It cannot be depended upon to kill anthrax spores through one layer of blanket. Formaldehyde is given off from its aqueous solution in very small amounts at ordinary temperatures. The evaporation of the solution in a closed container is slow and uncertain. In using this method, therefore, great care must be exercised to sprinkle the formalin uniformly, and in small drops. It is best to keep the container in a warm place to facilitate the evolution of the gas. Use not less than 4 c.c. of formalin, containing 40 per cent. formaldehyde, over every square foot of surface between every third layer of blankets or their equivalent. Somewhat less will suffice for linen and cotton goods. This means the use of from 50 to 100 c.c. per cubic foot. Increasing the amount from 2.5 c.c. to 4 c.c. per square foot does not correspondingly increase its power of penetration, but gives constant results. Increasing the time of exposure over twenty-four hours does not increase the penetrating power of the disinfectant. Pouring the liquid in one place, and splashing the liquid on with brushes will not suffice. The formalin must be carefully sprinkled in small drops and distributed uniformly over the surface, between many layers."

It is evident that in the Stewart Method penetration can only be expected where the formaldehyde has been carefully sprinkled in layers and confined in piles of bedding, baggage, etc., and even under these conditions only to the equivalent of three layers of blankets.

One would expect that, when a body pervious to gas was immersed in a gas, that in obedience to the law of diffusion the gas would diffuse through the body, always providing that the time element be sufficient. That formaldehyde does not do this we know, and the reason advanced is that the gas formaldehyde coming in contact with the fabric is converted into its solid polymeride trioxymethelene, and deposited on the surface of the fabric.

I have discovered that if the gas formaldehyde be mixed with vapor of carbolic acid, this tendency to polymerization does not seem to exist, and that the formaldehyde penetrates as one would expect, *i.e.* obeys the ordinary law of diffusion of gases.

The mixture which I have used is 75 per cent. of a 40 per cent. solution of formaldehyde and 25 per cent. of carbolic acid. I use 8 ounces of this mixture to 1,000 cubic feet of air space, and allow the room to remain closed twelve hours. I have used a retort to volatilize the mixture, but, as a matter of convenience, usually saturated a sheet and hung it up in the room to be disinfected (an ordinary sheet will hold about 6 ounces of the mixture).

The test objects used were those of the New York Health Department, consisting of a small thread of silk infected with a resistant strain of *B. pyocyaneus*. My exposures were always at night, from 7 P. M. until 7 A. M. I did not keep a detailed record of these tests, and, therefore, cannot give one, but I killed the bacteria on these test objects, when placed under the carpet; in the pocket of a winter coat and the coat tightly rolled and corded; through twelve layers of blankets; wrapped tightly in a handkerchief, and placed in a pasteboard box, the lid being placed tightly on the box; and in many other tests of this character. In no case did I get a growth in a test object exposed.

My results were so remarkable that I was inclined to question the accuracy of my own work. I asked Dr. F. M. Jeffries, Director of the Pathological Laboratory of the New York Polyclinic, to make tests for me. He tells me that he has not as yet tested the penetrative powers of these mixed gases farther than through seven layers of ordinary hospital blankets, but in all of his tests up through seven layers of blankets the bacteria have been killed.

New York, July 18, 1908.

OXYGEN IN SURGERY.

THIRIAR and his assistants were the first to employ oxygen extensively in phlegmons, furuncles, purulent joints, and in tuberculous peritonitis. They insufflated it locally, and claimed that it prevented an extension of the inflammation, diminished the virulence of the bacteria, neutralized toxins, stimulated the formation of granulation tissue, and caused an increased phagocytosis and leucocytosis. In spite, however, of individual good results obtained with oxygen, it never received an extensive trial. In an attempt to verify all that has been claimed for this method, Burkhardt (*Deutsche Zeitschrift für Chirurgie*, Vol. XCIII., No. 2) carried on a series of experiments in rabbits and dogs. Uninfected wounds were treated in the ordinary way, and with oxygen, the latter having been kept in constant contact with the wound. The oxygen caused a marked hyperemia and stimulated the formation of granulation tissue, but a wound so treated did not heal any quicker than one treated with a dry dressing. As regards its action on bacteria, he experimented only with staphylococci and streptococci. Agar plates were inoculated and kept in daylight at room temperature; some were kept in ordinary air, others under a jar containing concentrated oxygen. The latter showed only a few colonies at the end of four days, while the former were studded with them. The same experiment was carried out in a dark room with similar results, demonstrating that the oxygen, and not the sunlight, retarded the growth of the bacteria. When the same tests were made in the incubator, both plates showed considerable growth, and while the colonies on the plate which was kept in concentrated oxygen were a little less numerous, the difference was far less than when the experiments were carried out at room temperature. When animals were injected with bacteria grown in ordinary air and in oxygen, abscesses appeared in both cases, showing that the oxygen did not influence the virulence of the bacteria. Giving the animal a prophylactic intravenous or subcutaneous injection of oxygen did not change the result: abscesses formed or sepsis set in just the same. When the toxins of the bacteria grown in oxygen were injected into animals the resulting abscesses appeared later, and were smaller than those caused by toxins from bacteria grown in ordinary atmosphere. Hence toxins from bacteria grown in oxygen would seem to be a little less active. The toxin itself is not affected by oxygen; for after being exposed to concentrated oxygen for a few days it causes abscesses, when injected into animals, just as do toxins not so exposed.

Burkhardt injected oxygen into the peritoneal cavity, and found that it caused a hyperemia and diminished the absorptive power of the peritoneum. Twenty out of forty animals with general purulent peritonitis were treated with oxygen, the remaining twenty received no treatment. The death rate among those treated with oxygen was 45 per cent., among the others it was 65 per cent. He also treated five guinea pigs having tuberculous peritonitis with oxygen insufflations. While only one survived, the peritoneum showed fewer tubercles and less ascites than in the guinea pigs dying of tuberculous peritonitis, that were not treated with oxygen insufflations, although all originally received the same injection of tubercle bacilli. Remembering that oxygen treated by *x*-rays produces ozone, and that the latter is a bactericide, he insufflated the peritoneal cavity of rabbits having a general purulent staphylococcus peritonitis with oxygen, and immediately afterward exposed them to the *x*-rays for forty-five minutes. These animals all survived, while those not treated in this way, but injected with the same amount of a bouillon culture of staphylococci, died.

We may conclude from Burkhardt's experiments that oxygen therapy is probably of little avail in surgical conditions, excepting, possibly, in peritonitis. It retards the growth of bacteria slightly, but does not kill them. In the peritoneum it causes a hyperemia and diminishes absorption, and is, therefore, worth trying in both suppurative and tuberculous peritonitis. Other forms of treatment are frequently useless, and oxygen insufflations can do no harm. The use of ozone, on the other hand, either in concentrated form or produced by the action of the *x*-rays upon oxygen, seems worthy of trial in all septic infections, especially in those of the peritoneal cavity.

BIER'S HYPEREMIA IN GONORRHEAL ARTHRITIS.

ARTIFICIAL hyperemic treatment is now frequently employed in acute bacterial surgical infections which are located superficially. The treatment of infectious inflammation of joints involves greater responsibility, and though Bier reported good results in gonorrheal arthritis with artificial hyperemia as early as 1894, large statistics concerning this form of infection treated by Bier's method are rarely found in medical literature. In von Bergmann's clinic previous to 1904 gonorrheal joints were treated by immobilization; from that time on they were treated with artificial hyperemia produced by an elastic bandage. Forty patients were treated in this way and a complete history of each was published by Baetzner in the *Deutsche Zeitschrift für Chirurgie*, Volume 93, No. 1. In the acute stage of the disease he recommends leaving the bandage on from twenty to twenty-two hours. He warns against stopping the treatment too soon; in his cases it was employed for from five to ninety days, on an average twenty-six days for each case. Disappearance of pain was usually the first result of the treatment. As a rule the inflammatory symptoms disappear early, permitting painless active and

passive movements, as a result of which there is little atrophy of the muscles and early good function of the joint. Thirteen joints, in all but five of which the inflammation was of the severe phlegmonous type, were treated within the first week of the disease, the treatment lasting from eight days to six weeks. All were cured and none showed any disturbance of function. In the remaining twenty-seven patients treatment was begun from ten days to twenty-one weeks after the onset of symptoms; they had either received no previous treatment, or the latter had done no good. Of these twenty-seven the best results were obtained in those cases in which acute symptoms were still present, but even some of those without acute symptoms were improved, the treatment causing a softening of the chronically inflamed tissues, thus making them more amenable to massage. Twelve of the twenty-seven were discharged with no disturbance of function, nine had slight disturbances, while in six the range of motion was only half that of the normal joint. In no patient did a joint become ankylosed.

Baetzner believes that cases not improved by the Bier treatment are those in which the technique was not properly carried out. Too great stress cannot be laid on proper technique, for often the bandage is put on too tightly or we see the treatment combined with an ice bag on the diseased joint, the one causing a hyperemia the other an anemia. The histories of these cases also show that the result as regards function and duration of disease is best when the treatment is begun early. With the older method of treatment, *i.e.* immobilization, more cases of ankylosis were seen; one never knew when to remove the fixation bandages; if they were removed too early and motion permitted an acute exacerbation was liable to set in, if left on too long there was a greater tendency to ankylosis. The hyperemic treatment on the other hand diminishes pain and thus renders possible gentle active and passive motion with less chance of any functional disturbance. Hyperemic treatment makes greater demands on the physician's time than immobilization, but the result amply rewards him for his trouble. The rapid abatement of pain in Baetzner's cases must convince even the most skeptical of the great truth underlying Bier's teachings, namely, that by artificially increasing the symptoms of inflammation we hasten cure.

ALIMENTARY LEVULOSURIA.

The methods of testing the functional activity of various organs have not reached perfection, except, possibly, with respect to the stomach. Investigations as to whether the liver functionates properly are not of recent date. Many methods of testing its functional activity have been suggested, but nearly all of them soon fell into disrepute. Animal experiments have demonstrated that levulose is changed to dextrose only in the liver. This led H. Sachs to suggest feeding levulose in order to test the functional activity of this organ, and when it was partly excreted by the kidneys as levulose, he concluded that the liver was not functionating properly. Numerous investigators have since proven that there exists a parenchymatous degeneration of the liver when levulose is excreted by the kidneys.

Sabatowski tried the test in seventy-eight patients suffering from various diseases, and published his results in the *Wiener klinische Wochenschrift* of May 28, 1908. He administered 100 grams of levulose in lemonade after the patient had been on a diet free from carbohydrates for twenty-four hours. The urine was tested by Seliwanow's method. In twenty patients with cirrhosis he found it negative only twice. In only one out of eight catarrhal jaundice patients did he find no levulose in the urine. Levulose was found in all patients suffering from infectious diseases. In patients suffering from uncompensated heart lesions with enlarged liver no levulose was found in the urine. His experiments show that levulose is excreted by the kidneys in patients in whom there is parenchymatous degeneration of the liver. The amount of levulose in the urine is, however, no criterion of the extent of the degeneration, for there is no way of telling how much levulose was decomposed in the stomach or intestine before it reached the liver. As it is found in the urine in most infectious diseases, the test is but rarely of value as a differential diagnostic measure. It might, however, be used to differentiate ascites due to cirrhosis from ascites due to tuberculous peritonitis. Other than that, the routine application of the levulose test can be of little value clinically.

Chondrotomy in Apex Tuberculosis.

Many attempts have been made to explain the frequency with which the apices of the lungs are attacked by tuberculous disease, the most satisfactory theories being founded upon the little ventilation of the apices in comparison with other parts of the pulmonary tissue, and the upward course of the bronchial division favoring the deposition of infectious material that has been inspired. Freund and Hart's researches have shown that maldevelopment of the first rib, consisting of shortening and early ossification of its cartilage predispose very markedly to infection of the apices, both the size of the upper aperture of the thorax and the movements of the apices in respiration being seriously diminished by these conditions. Both authors have found that in many cases of healed tuberculous disease of the apices false joints have formed at the cartilages of the first rib, such joints making up for the mechanical interference with respiration due to the maldevelopment of the rib, and Freund has proposed to imitate this conservative process of the organism by the artificial production of a false joint. In the *Münchener medizinische Wochenschrift* for June 23, 1908, Dr. Hans Seidel tells of his experience in the application of Freund's principle. In two patients suffering from apical tuberculosis the mechanical interference with the ventilation of the apices was quite marked; resection of portions of the first and escond ribs was carried out, and the patients showed rapid and progressive amelioration of symptoms and the disappearance of physical signs of apical tuberculosis, gained in weight, and were discharged cured, the usual measures of treating tuberculosis proving quite effective in their cases after the operations. Dr. Seidel thinks that Freund's operation is indicated in all young individuals showing stenosis of the upper aperture of the thorax and tuberculous disease of the apices, and in older persons showing

ossification of the first rib cartilage and diminished movement of the first rib, especially if the usual treatment for tuberculosis has proved ineffectual, while the lesions seem to be confined to the upper portions of the lungs. Of course, the procedure recommended by Freund and Seidel is at present only in its experimental stage, and in any case is to be used in the presence of special indications in no way taking the place of the usual measures of treatment of tuberculous lesions. Further experience with it, however, may entitle it to consideration as one of the very few surgical procedures open to us in the treatment of localized tuberculosis.

Acute Dilatation of the Heart.

It is the general opinion of physicians that great physical exertion often results in acute dilatation of the heart, and almost every practitioner believes he has seen such cases as proved by the position of the apex beat and the percussion of the heart borders. Schott of Nauheim thinks indeed that such dilatation is a physiological phenomenon that may be observed in healthy persons after exertion not exceeding the usual limits of their daily occupations, and has used *x*-ray pictures as evidence of such a phenomenon. Writing in the *Münchener medizinische Wochenschrift* for June 23, 1908, Dr. Moritz seriously questions the correctness of the usual view held by the profession, as well as the value of the proofs used by Schott and his followers to justify the assumption that dilatation is a frequent event. The position of the heart previous to the occurrence of "dilatation" is not always known to the physician who imagines he has observed it after some unusual exertion, while *x*-ray pictures are, of course, only shadows, and may quite mislead the observer as to the position of the landmarks. Dr. Moritz had a good opportunity to study the hearts of several wrestlers after the severe exertion which their occupation demands. In no case was there any dilatation of the heart to be shown, and like results were noted in several bicycle riders after some very fast riding. Later, he repeated his observations, using the orthodiagrammatic methods of determining the size of the heart before and after the exertion of a bicycle race. Indeed, Moritz claimed to have noted even a diminution in the size of the heart following moderate or severe exertion. The possibility of an acute dilatation is not denied by the author, but such a phenomenon, according to him, is a sign that the heart is not free from some pathological defects.

Subaqueous Examination and Treatment in Gynecology and Obstetrics.

The reflex spasm of abdominal muscles or their voluntary rigidity in nervous or apprehensive patients may interfere very much both with the correct diagnosis of many abdominal and pelvic diseases as well as with the treatment of them by manipulation. This is especially noticeable in the various mechanical procedures used in the correction of malpositions of the uterus in gynecology. In a recent article (*Berliner klinische Wochenschrift*, June 22, 1908), Dr. O. Tuszkai warmly defends the examination and the treatment of many obstetrical and gynecological patients under the water of a warm bath. With this method pregnancy may be diagnosed much earlier than usually, such physical signs as the great difference between the soft lower uterine segment and the resistant fundus containing the young ovum, that form the bases of Hegar's sign of pregnancy, being well appreciated as early as the sixth week. The fetal parts are very easily mapped out in the later months if the examination is made under water, and accordingly the diagnosis of malpositions may be made early. But especially useful such immersion proved to be in the diagnosis of gynecological diseases, ovarian cysts and fibroids of the uterus, in the reposition of the misplaced uterus. In addition, several inflammatory lesions of the pelvis which usually would have required the use of an anesthetic for a satisfactory examination could be painlessly and thoroughly examined under warm water. Of course, regular use of this method of examination in the office practice of a gynecologist would require special arrangements of rooms, water supply, etc. According to Dr. Tuszkai, however, the advantages are such as well to repay the extra trouble and expense involved in carrying out examinations and treatment under warm water; indeed, he gives full directions in his article in reference to the mechanical arrangements required by the technique of examinations made by him.

Mr. Bok, Hygienist.

The *Ladies' Home Journal* of Philadelphia, if it were taken seriously by its readers, would be a power for evil in the land. Fortunately, it is known to be given to foolish utterances, so the ladies read it and smile and forget when it tells them to avoid the drug doctors who poison them by prescribing quack remedies. Sometimes, however, it displays such outrageous ignorance and gives pernicious advice with such an air of scientific cocksureness that a word of caution to those whom it would mislead is perhaps necessary. In the June issue the literary editor, to whom, for some unknown reason, questions of hygiene seem to be referred, says, in answer to the query of an anxious reader, that boiled water is unsafe to drink because a temperature of 212° does not always kill all the bacteria which it may under exceptional circumstances contain. He admits, on the authority of an anonymous French experimenter, that most germs are killed in a few minutes by such a temperature, but, evidently preferring no bread to nine-tenths of a loaf, he condemns the use of boiled water because an occasional spore may escape destruction in the process. He omits to say, probably because he doesn't know, that the typhoid bacillus and the germs of dysentery, the presence of which constitutes the chief danger in the drinking of unboiled water from doubtful sources, are absolutely killed by a temperature of 212°, and that the microorganisms which escape find no congenial soil for their development in the alimentary canal. This negative condemnation of boiled water would be bad enough, if his readers took the hygienic oracle's words seriously, but he descends to absolute imbecility in his closing paragraph: "Ordinary boiled water is liable to cause numerous severe and often dangerous stomach and intestinal maladies." It is disheartening to find a journal with pretensions to sanity giving publicity to such medieval drivel.

Charitable Bequests.—Under the will of the late Mrs. Eugenia Shumway of Polo, Ill., the Deaconess' Home and Training School of the Wesley Hospital of Chicago, and the Old People's Home at Edgewater receive each $1,000.

News of the Week.

The Democratic Health Plank.—The Democratic Convention, in session at Denver during the past week, inserted the following plank in its platform: "We advocate the organization of all existing national public health agencies into a National Bureau of Public Health, with such power over sanitary conditions connected with factories, mines, tenements, child labor, and other such subjects as are properly within the jurisdiction of the Federal Government and do not interfere with the power of the States controlling public health agencies."

International Classification of Causes of Death.—The Department of Commerce and Labor, Bureau of the Census, announces the second decennial revision next year of the International Classification of Causes of Death, which is intended for the purposes of morbidity and hospital returns as well as for mortality statistics. This system, which was formerly known as the "Bertillon system," was recommended by a committee of the International Statistical Institute in 1893, by the American Public Health Association in 1898, and at the recent meeting in Chicago of the American Medical Association. It is employed by the United States Bureau of the Census, by all registration States, and by nearly all registration cities in the United States. It is used by a number of European countries, by all countries in North and South America, and by Japan. The preliminary announcement just issued by Dr. Bertillon, at the request of the Ministry of Foreign Affairs of the French Government, indicates that the year 1909 has been chosen for the revision largely to facilitate the use of the revised classification in connection with the mortality statistics of the census year 1910 in the United States, and it is hoped that the profession generally will show appreciation of this action by hearty cooperation. Many suggestions from American physicians were incorporated in the first revision, but the progress of medical science and the test of practical use will indicate desirable changes. The Director of the Census will send a pamphlet on "Relation of Physicians to Mortality Statistics," containing an outline of the classification, upon request.

Danger from Flies.—The Chicago Health Department, in its weekly bulletin, speaks of the danger from the common house fly, and urges that flies be kept out of homes and away from food, thus avoiding the diarrheal disturbances and typhoid fever, which may follow as the result of having so many of these pests in houses. The bulletin points out that flies may be the conveyers of scarlet fever, diphtheria, tuberculosis, and other infectious diseases.

Mosquitos and Flies Must Go.—The doom of house flies and mosquitos has been sounded in the announcement of the beginning of a national campaign against these pests by the Government Bureau of Insects, which will cover the entire country. The extermination of the house fly is a simple matter, as it is strictly local and never goes far from the place where it is hatched. Practically all house flies are bred in stables. For the mosquito, a general control by the State is deemed advisable because of the fact that certain species are migratory and are liable to appear in multitudinous swarms in places far from their breeding areas, causing profound discouragement to local efforts toward extermination.

The Samuel D. Gross Prize.—The Philadelphia Academy of Surgery announces that essays in competition for the Samuel D. Gross Prize of fifteen hundred dollars will be received until January 1, 1910. This prize is awarded every five years to the writer of the best original essay, not exceeding in length one hundred and fifty printed octavo pages, and illustrating some subject in surgical pathology or surgical practice, founded upon original investigation, the candidates for the prizes to be American citizens. Essays submitted for the competition must be typewritten, in English, and by a single author, and should be sent to the "Trustees of the Samuel D. Gross Prize of Philadelphia Academy of Surgery, care of the College of Physicians, 219 South Thirteenth street, Philadelphia." Essays should be distinguished by a motto and accompanied by a sealed envelope bearing the same motto and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay. The committee reserves the right to make no award if the essays submitted are not considered worthy of the prize.

Tuberculosis Warfare. — The fight against tuberculosis is being carried on as energetically in the West as in the East. In San Francisco a Society for the Study and Prevention of Tuberculosis has recently been formed, many laymen and women uniting with the physicians. In St. Louis, outdoor meetings are being held in the parks under the auspices of the St. Louis Society for the Relief and Prevention of Tuberculosis. The program usually begins with a phonograph and moving picture entertainment, and the lecture is illustrated with lantern slides. During 1907, thirteen of such meetings were held, with an estimated attendance of 50,000. "Hopewell," the sanatorium for the treatment of tuberculosis which is being erected by the Board of Charities of Minneapolis, will be ready on August 1. The building is being erected on the plan of a model which won first prize at an international tuberculosis congress, and is of simple and inexpensive construction. In Lansing, Mich., the Board of Health is sending large posters to the owners of factories and shops, with the request that they be prominently displayed. Rules and suggestions for the prevention of the disease and for its cure are clearly set forth. These are but four examples of a campaign of education and relief which is sweeping over the entire country.

Safe Street Car Fenders.—During the next three months the Public Service Commission of New York will make a series of tests of fenders and wheel guards for surface cars. Manufacturers and inventors of safety appliances from all over are to be asked to submit their devices for practical demonstration. The competition is to decide what types are best adapted for use in the city. The street railroads have been killing an average of forty to fifty persons a month, besides crippling many more, and it is apparent that most of these accidents are due to imperfect fenders and wheel guards. In order to obtain practical results, the actual conditions of street traffic will be reproduced in the tests as far as possible, and dummies will be used to represent persons, one weighing 170 pounds, one 120 pounds, and one 50 pounds. Ten different tests with each dummy will be called for, including upright positions facing toward and away from the car, and prone positions in various attitudes.

A Simple Icebox.—Because hundreds of chil-

dren are made ill each summer by drinking milk which has been standing at room temperature, and is consequently swarming with bacteria, the Milk Committee of the Association for Improving the Condition of the Poor is introducing a cheap and novel form of icebox into the districts where they already have established milk depots. Dr. Alfred F. Hess is the inventor of the contrivance, which is made by placing a tin pail into a soap box and packing the intervening space tightly with sawdust or newspapers. A smaller pail is then placed inside the first. This contains a piece of ice and is half filled with water. The whole is covered with a thick layer of newspapers. A bottle of milk placed in the inner pail will remain at a temperature of 40° for twenty-four hours, and the milk will keep sweet. While it was hoped that the milk depots thus far established might be made self-supporting, but few of the users have as yet been able to pay even the small cost price, and the depots are thus almost entirely dependent upon public subscriptions. It is estimated that twenty-five cents a week will provide one baby with properly modified milk and also the advisory services of a doctor and nurse.

Baby Foods.—Announcement is made in Washington that Dr. H. W. Wiley, the head of the Bureau of Food and Drug Inspection of the Department of Agriculture, will shortly begin a comprehensive investigation into the composition of the various prepared foods for infants on the market. The reason for the investigation is said to lie in the number of complaints received by the Bureau from mothers whose children have failed to thrive on some of the much-advertised preparations. Prepared foods for cattle and for poultry are also to be investigated.

Day Nursery Incorporated.—The New York State Board of Charities, on July 8, approved the incorporation of the Washington Heights Day Nursery of New York City, and of the Home for Jewish Children of Brooklyn. The Board also received a report of the special committee named to investigate the private hospitals in New York City which are receiving public moneys from the Department of Public Charities. The report showed that the charges made by the Superintendent of Mount Sinai Hospital that his institution had been discriminated against were not sustained.

Doctors Honored.—At its recent commencement, the University of Michigan conferred the degree of M.A. on Dr. Walter Courtney of Brainerd, Minn.; of D.Sc. on Dr. Franklin P. Mall of Johns Hopkins University, and of D.Sc. on Dr. William J. Mayo of Rochester, Minn. All were members of the medical class of 1883.

Dr. Wm. A. Evans, Health Commissioner of Chicago, has been added to the faculty of the Northwestern University Medical School, and henceforth will hold the Chair of Sanitary Science. Dr. Evans' practical work as Health Commissioner of Chicago has well fitted him to teach with authority municipal sanitation and all the problems that arise in that connection. Dr. Evans has been Professor of Pathology in the Medical Department of the University of Illinois for seventeen years.

Dr. Jacques Loeb of the University of California and Dr. Charles Sedgwick Minot of the Harvard Medical School have been appointed corresponding members of the Physico-Medical Society of Vienna.

Liquor Prescriptions.—North Carolina having joined the ranks of Prohibition States by passing an act making the sale of intoxicating liquors illegal except on a physician's prescription, the State Medical Society at a recent meeting at Winston, N. C., passed a resolution condemning as unprofessional and grossly immoral any lax or unfaithful conduct of its members in exercising the privileges conferred by the law, and urging upon the State Board of Medical Examiners the duty of revoking the license to practise of any physician proved guilty of abusing the privilege accorded to him in the prescribing of intoxicants.

New York Public Baths.—The opening of the river baths on July 6, during a period of very severe heat, proved a boon to hundreds who were able to make use of them. Nine of the river baths were ready and two others will shortly be opened. Besides these, there are eight public baths in the city which are open from 5 in the morning until 9 at night, the first part of the day for men, the latter part for women. These were opened on July 5. The University Settlement, at Eldridge and Rivington streets, having been able through the generosity of Mr. James Speyer to add sixteen new baths to the existing twenty-seven, is now giving baths to over 1,000 persons a day. For these baths a charge of five cents is made, to cover the cost of soap and towel.

Cocaine Peddlers Arrested.—Two prisoners charged with peddling cocaine by an inspector of foods and drugs of the Department of Health were recently arraigned in New York and held in $1,000 bail each for trial. It was stated that the inspectors were on the trail of a Brooklyn man whose business it was to supply cocaine to agents who peddled it in the vicinity of the Pennsylvania tunnel excavations. In Pennsylvania, during June, a man and a woman, both colored, charged with being ring leaders in the cocaine traffic in Harrisburg, were arrested, convicted, and sentenced to six months in jail.

Horseflesh as Food.—Vienna will shortly open new municipal slaughter houses for the killing of horses. There has been a steady increase in the consumption of horseflesh in the city, over 20,000 horses having been slaughtered for food during the last year. Most of the flesh is made into sausages of various kinds. The new buildings cover an area of 3,300 square yards and provide stabling for 200 horses and stalls for killing fifty-nine, each fitted with hoisting apparatus.

London Approves Pasteurization.—The public health committee of the London County Council has presented a complimentary report on the demonstrations given at the temporary laboratory established by Mr. Nathan Straus, for pasteurizing milk. The question of furthering the use of pasteurized milk was discussed, and it was the sense of the members that comprehensive plans for carrying out the Straus system should be formulated.

Erection of a New Dispensary.—The Northwestern University Medical School of Chicago will soon build a dispensary on Calumet avenue, north of Mercy Hospital, the property having been acquired by Dr. John B. Murphy for the institution, and conveyed by him to the university for $7,801, June 26.

The University of Madrid will celebrate the four hundredth anniversary of its foundation on October 18, and extensive preparations are being made for the event.

The Sea Breeze Home for mothers and children at Coney Island closed, on July 11, the biggest week in its history. On one day 405, the highest number, were cared for, which made it necessary for the older boys to camp out on the beach. Lack of funds prevents the enlargement of the home, which is desirable. The home accommodates both those who go for the day and those who go to stay for one or two weeks.

Charitable Bequests.—St. Rose's Free Home for Incurable Cancer at 420 Cherry street, New York, receives $5,000 under the will of the late John G. Hecksher.

The Physician's Automobile Association of the Oranges has recently been formed in Orange, N. J., with a charter membership of forty physicians who are advocates of the automobile. The officers are: *President*, Dr. Edgar C. Siebert; *Vice-President*, Dr. Palmer A. Potter; *Secretary*, Dr. Stephen G. Lee; *Treasurer*, Dr. Arthur W. Bingham. The Board of Governors is composed of Drs. Thomas W. Harvey, Mefford Runyon, and Richard D. Freeman.

Association of Military Surgeons.—The date of the annual meeting of the Association of Military Surgeons of the United States has been changed to October 13, 14, 15, and 16, 1908. The meeting will be held at Atlanta, Ga., as first announced.

The New Hampshire Homeopathic Medical Society, at its annual meeting on June 24, elected the following officers for the ensuing year: *President*, J. E. Willis of Somersworth; *Vice-President*, C. A. Sturtevant, Manchester; *Secretary*, R. V. Sweet, Rochester; *Treasurer*, Herman Christophe, Manchester.

The Medical Society of the State of North Carolina at its fifty-fifth annual meeting, elected the following officers: *President*, Dr. Jacob F. Highsmith, Fayetteville; *Vice-Presidents*, Drs. C. M. Poole, Salisbury, and Daniel A. Dees, Bayboro.

The National Institute of Homeopathy held its sixty-fourth annual meeting in Kansas City during June. The following officers were elected: *President*, Dr. William Davis Foster, Kansas City; *Vice-Presidents*, Drs. T. H. Carmichael, Germantown, Pa., and Joseph Hensley, Oklahoma City; *Secretary*, Dr. Frank Kraft, Cleveland; *Treasurer*, Dr. T. Franklin Smith, New York; *Registrar*, Dr. Joseph H. Ball, Bay City, Mich.

Christian Science Death.—An eleven-months-old child died on July 11 in New Jersey from convulsions, after medical attendance had been refused and the services of a Christian Science "healer" secured.

A New State Journal.—The first number of the *Journal of the Oklahoma State Medical Association* appeared this month. The contents include, besides the original articles, case reports, etc., an account of the meeting of the State Association and the President's address. The journal is of convenient size and is a credit to the association.

Baltimore Medical College.—A laboratory and library building is shortly to be erected on the ground purchased by the Baltimore Medical College some months ago. Provision is to be made for three lecture halls with a seating capacity of 200 each, and for pathological, physiological, chemical, and physical laboratories. The building, which will be of brick, and four stories high, will cost about $50,000.

Obituary Notes.—Dr. Lewis Barnes of Oxford, Conn., died at his home on July 5, at the age of eighty-four years. Dr. Barnes was graduated from the Yale Medical School in 1847, and practised for nearly sixty years. For twenty-three years he was Judge of Probate, and at one time was President of the medical society of his county.

Dr. Allan Clarke Hutton of New Brunswick, N. J., died on July 7, at the age of sixty-seven years. Dr. Hutton was a graduate of the College of Physicians and Surgeons, New York, and was for many years Treasurer of the New Jersey Microscopical Society.

Dr. George Jenkins Preston of Baltimore, Md., died at his home on June 17, after a long illness, aged forty-nine years. Dr. Preston was graduated from the medical department of the University of Pennsylvania in 1883, and since 1890 had been Professor of Physiology and Nervous Diseases in the College of Physicians and Surgeons of Baltimore, and since 1898 Secretary of the Maryland Lunacy Commission. He was a widely known alienist and neurologist to several hospitals.

Dr. Maximilian F. C. Drescher of Brooklyn, N. Y., died at his home on July 7, aged forty-eight years. He was graduated from the Long Island College Hospital in 1891, and was a member of the Kings County Medical Society.

Dr. James Hoffman, a well-known homeopathic physician of Jersey City, died suddenly on July 8, aged about fifty-five years. He was graduated from the Hahnemann College of Philadelphia in 1885.

Dr. Felix H. Coyle of New York died suddenly on June 11. Dr. Coyle was graduated from the College of Physicians and Surgeons of Baltimore in 1886, and had recently given up practice owing to severe attacks of rheumatism.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

DEFENSE OF RESEARCH—HOSPITAL FUNDS—LEAGUE OF MERCY—KING'S BIRTHDAY HONORS—PROVIDENT DISPENSARIES—ST. BARTHOLOMEW'S HOSPITAL—OBITUARY.

London, June 29, 1908.

The Research Defense Society, about which I have previously written, may now be regarded as firmly established. It has already enrolled 1,290 members, and an inaugural meeting was held on Friday last. Lord Cromer, president, after the report had been adopted, delivered an address in which he maintained that experiments on living animals could be defended on two grounds. In the first place it had to be shown that they had produced valuable results; in the second that they were conducted in a manner so as to minimize or to obviate entirely suffering. Both propositions had been proved up to the hilt, and with extremists who said it was never right to destroy animal life they must differ, for the full application of such a theory would lead to impossible conclusions. Great misapprehension existed as to the extent of experimentation. In 1907 there were 73,000 so-called experiments, but 96.5 per cent. were inoculations, almost entirely painless, and not operations at all. Broadly speaking, he declared that the small amount of suffering was a price that might justifiably be paid for the enormous amount of suffering which was relieved.

Sir Thomas Barlow said that while the British people could give their confidence to the rank and file of the medical profession he wished to testify that they had received their strength and power from their experimenting brethren. The society had come right down into the open, would put everything on the table and let the people know what was done, what care was taken, the kind of experiments made, and their bearings on medicine and surgery. One of the best things

that Mr. Chamberlain did at the Colonial Office was what he did for the study of tropical diseases.

Lord Robert Cecil, M. P., said if it was held that pain must never be inflicted on animals the consequences would be unexpected perhaps by those who held that view. Riding and driving horses and beating disobedient dogs must be forbidden. How could animals be imprisoned for life in the zoological gardens? A reasonable probability of saving human life and diminishing human pain was a valid justification of experimentation.

Mr. Walter Long, M. P., referred to the stamping out of rabies when he was at the head of the Local Government Board, and declared they would not have dared to attempt it but for the precise knowledge of the experts, on whose advice they relied. It was no use making discoveries if the years of anxious labor were to be undone by one foolish act.

Dr. C. J. Martin, F.R.S., made an impression on the audience when he told them that in the return of vivisections above 40,000 were inoculations of mice in the study of cancer, a disease from which one in eleven men over thirty-five might expect to die and one in eight of women. It might be many years, he said, before the cancer problem was solved, but experimentation had led to a clearer conception of it than was ever possessed before.

Mr. Butlin repudiated the slander that experimentation made men callous and referred to Lord Lister, Sir J. Paget and others, the mention of whose names sufficed to disprove the calumny. He congratulated the society on having so eminent a president.

The hospital funds are just now meeting with criticism which may perhaps be to some extent beneficial, but a number of objections to their proceedings arise from misunderstandings. The managers of the King Edward Fund have just issued an important circular to the hospitals, reminding them of the resolution sanctioned by the General Council in 1903, which requested them, before reconstructing or enlarging, to submit their intentions to the Fund.

The new circular sets forth the full purport of the resolution and among other points states that the information requested includes: (1) Reasons and considerations leading to the proposed changes; (2) nature of proposals, with any outline sketch—not detailed architects' plans: (3) accommodation to be provided compared with present work; (4) rent and tenure; (5) estimated cost; (6) resources to meet cost; (7) prospect of providing any increased cost of maintenance: (8) approximate date of beginning and finishing the proposed work.

Similar information is requested from the promoters of new hospitals who may contemplate applying to the Fund in future, but it is distinctly pointed out that the Fund does not assist the foundation of new institutions nor receive applications from any that have not been carried on properly for three years or more.

Such, briefly stated, are the conditions of help imposed by the managers of the Fund, and I can scarcely look on them as unreasonable. There are, however, many who are saying that the managers are assuming a position to which they are not entitled and that there is a growing disposition to override the institutions to which they contribute. It is, of course, to be expected that institutions which have obtained no grant or a less amount than they expected should feel some dissatisfaction. Some, too, resent recommendations which they regard as interference, and cite policy of promoting amalgamation of small institutions favored by the Fund. But I believe this policy meets with general approval, although some think it has been pushed rather far. These critics, however, are for the most part connected with the smaller, similar, not to say competitive, hospitals, of which we certainly have too many, and it would be a great pity to encourage them all to struggle on in the fight for subscriptions.

The League of Mercy may be regarded as an offshoot of the King's Fund. It was founded in 1899. Since then it has gathered nearly £100,000 for the hospitals of London and the Home Counties, and this money it passes on to the King's Fund for distribution. On Wednesday the Prince and Princess of Wales gave a garden party in the grounds of Marlborough House for the members of the League, and the Prince conferred on about fifty the decoration of the Order of Mercy, the awards having been sanctioned by the King.

Lists of honors and promotions in connection with the King's birthday were issued last night. Many people are smiling to find four new peerages added by the Government, which promised to abolish the House of Peers, but which had previously added a greater number than any previous Government in a similar period. That, however, does not concern medical news. But it is well to hear that the profession is not quite forgotten. Lauder Brunton (already a Knight) becomes a Baronet; so does Watson Cheyne. Among the new Knights are Col. D. Bruce and Dr. Burnet. The claims of all are well known.

A return of the new civil list pensions granted in the year ending 31st March appears this morning. It includes Ray Lankester and J. Hall-Edwards (the victim of *x*-rays).

Thrift and providence are at a discount with our present Government. Their old-age pension scheme is considered by their opponents to tend rather to encourage improvidence. As to medical aid for the less well-to-do, the provident system has always had many supporters, both within and without our ranks. The first association established to promote provident medical institutions appears to have been started in 1827. Since then about forty provident dispensaries have been established in London. The majority of these have, I think, been due to the work of the Metropolitan Provident Medical Association, which dates from about twenty years ago. A meeting was held in its support on Tuesday and was well attended. Viscount Milner spoke in its favor, urging that some system of insurance forms the best provision against a time of sickness for all those whose means are so limited that such a time is likely to be overwhelming. Such provision secures efficient medical help for the poor and thrifty. These provident dispensaries, his Lordship maintained, were therefore doing valuable work and deserved the support of all interested in hospitals. They were able to take charge of cases which crowded too many outpatient departments and so to set the hospitals free to do their proper work.

Lord Ludlow (treasurer) and five "almoners" of St. Bartholomew's Hospital have resigned their posts in consequence of a unanimous recommendation they made not being adopted by the Court of Governors. The Court, in accepting Lord Ludlow's resignation, recorded its deep appreciation of his services and its grateful acknowledgment of the advantages that have accrued to the institution as the result of the reforms instituted by him in the management of the estates and in the internal administration of its affairs, which "cannot be overestimated."

The foregoing significant communication appeared in the papers nearly a fortnight ago, but no further light has been shed on it.

Last week I recorded the death of a centenarian following nonogenarians of the week before. Now I have to report the loss, at the early age of 38, of Dr. Bertram Abrahams, assistant physician and lecturer on physiology at the Westminster Hospital. His career as a student at University College, and since, has been a brilliant one. He took the B.Sc., in 1890, M.B. in 1895, with first-class honors. He won the Liston prize essay on the "Surgery of the Gall-Bladder" and contributed several articles to Allchin's Manual, the Clinical and the Pathological Transactions, etc. He had appeared to be in delicate health for some time.

Dr. Edwin Rickands, J.P., consulting physician to the Birmingham General Hospital, and president of the Medical Institute, died on the 11th inst., aged 66. He was an Oxford graduate, M. A. 1865, M.B. 1872, took also F.R.C.S., Eng., 1870, the M.R.C.P., 1874, and was elected Fellow in 1886.

OUR LETTER FROM THE PHILIPPINES.

From Our Special Correspondent.

PERIODICITY OF PLAGUE RECRUDESCENCES—INCREASE OF THE DISEASE IN CHINESE PORTS—CHOLERA IN THE PHILIPPINES—SMALLPOX—PERSONAL.

MANILA, P. I., May 29, 1908.

OWING to the reappearance of plague in Amoy, Canton, and other Chinese ports, which takes place with clocklike regularity each year during the month of May, the Philippine Islands have again quarantined against those Chinese ports at which no regular officers of the United States Public Health and Marine Hospital Service are stationed and at which no adequate facilities exist for disinfection of vessels prior to departure. The period of detention is fixed at seven days after disinfection in the Philippine Islands is completed.

So far as is known, no satisfactory explanation has yet been offered as to why the disease should make its appearance so regularly at this time of the year, and again completely disappear, apparently, without any

measures having been taken to suppress it during the months of October and November. It would seem that this is a matter that merits attention and that some light could be thrown upon the subject if it could be definitely ascertained whether rats or fleas are more likely to breed in larger numbers or more capable of transmitting plague bacillus during the month referred to.

In Canton much more plague is said to be present than is ordinarily the case. An estimate of this kind, however, must be a mere conjecture, because the municipal conditions in Canton are such that it is impossible to know just how many cases take place in a given time.

In the port of Hongkong for the two weeks ending May 22, 1908, 200 cases and 141 deaths have been reported. During a corresponding period last year there were only 24 cases and 14 deaths reported.

Cholera has again made its appearance in rather severe form in the Philippine Islands in the provinces of Capiz and Pangasinan. In the former province there have been during the past few weeks a total of 236 cases and 191 deaths, while in the latter province there have been 531 cases and 354 deaths. In view of the continuous demand which is constantly made for greater autonomy in the Philippines, it has been the policy of the Insular Bureau of Health to permit the municipalities in which the disease appears to combat it with their own officials, and only to take charge when the disease threatens to spread from one province to another. While this policy has not been as successful as could be desired in eradicating the disease, it has, however, placed the Insular Bureau of Health in a much more favorable attitude than it has appeared for some years. Instead of a popular outcry being raised against the measures which have been necessary in suppressing the cholera, it now finds itself in the position of having appeals come in from the municipalities to send its officials there in order to combat the outbreaks. It is believed that the poorer results obtained at the outset will be more than offset by the more hearty aid which will be given later on by the municipal officials in whose district this disease makes its appearance.

The smallpox outbreak which has existed for a number of weeks in Manila has apparently about come to a close. The enormous amount of vaccination which was done and the onset of the rainy season have, no doubt, contributed to this result.

A review of the outbreaks of smallpox which have occurred here during the last fifty years shows almost conclusively that the disease disappears as a rule within a few weeks after the onset of the rainy season, which is strong, presumptive evidence that the disease is probably aerially conveyed. This also coincides with the experience which has been had with the hospital ships which are anchored in the Thames near London, where it has been noticed for many years that cases of smallpox seem to occur more frequently along the lee shore from where these smallpox hospital ships are anchored.

Assistant Surgeon H. M. Manning, of the Public Health and Marine Hospital Service, who has been on duty in the Philippines as Quarantine Officer at the port of Cebu for the past few years, has been relieved from further duty in the Philippine Islands and sailed May 14 on the United States transport Sherman for San Francisco.

Dr. Aron of Berlin, Germany, the physiologist, has accepted the position of Professor of Physiology in the Philippine Medical School, and is due to arrive here early in July.

OUR CANADIAN LETTER.

(From Our Special Correspondent.)

MEDICAL ASSOCIATIONS IN CANADA—AGITATION FOR THE PREVENTION OF CANCER—McGILL MEDICAL JOURNAL CLUB—MEETING OF ASSOCIATION OF FRENCH PHYSICIANS—REGULATIONS TO LICENSE PURE MILK SUPPLY IN CANADA—VITAL STATISTICS.

TORONTO, June 27, 1908.

THE meetings of the principal medical associations in Canada have been held at earlier dates than usual this year, and the meetings have been of more than ordinary interest. The Ontario Association at Hamilton was more largely attended than any previous meeting in the twenty-eight years of its history. This association has held only four of its meetings outside of Toronto, the capital of the province, it being considered that meetings of such an organization would always be more successful when convened at the principal city. The large attendance this year disproves that idea, and in future the place of meeting will probably alternate between Toronto and other cities of Ontario. A large measure of credit for the success of this year's meeting is due to the energy of the president, Dr. Ingersoll Olmsted of Hamilton, and the local committees. The program presented was not only excellent in character, but the sections were so arranged as to present discussions that were of more than usual interest. The meeting was extended this year to fully take up three days, and a large field of work was covered. The 1908 meeting of the Ontario Medical was certainly one of the best. The president for the coming year is Dr. Herbert J. Hamilton of Toronto.

The Canadian Medical Association meeting at Ottawa was not as largely attended this year as usual, although large representations were present from Montreal, Toronto and Ottawa. It was perhaps unfortunate that the date of the meeting was fixed in such proximity to that of the Ontario Medical Association, which had been so largely attended. This will probably never occur again, for by the new constitution just adopted it has been arranged that whenever the Canadian Medical Association meets the Provincial Association shall for that year not convene except in connection with the meeting of the parent organization. This change will probably prove of great advantage. The meeting at Ottawa last week, while not so largely attended as usual, had a program that was highly appreciated, and the president, Dr. Montizambert, was loyally supported by his confrères in Ottawa in making the arrangements perfect in every respect. The address in medicine, "The Value of the Reflexes in Diagnosis," was given by Dr. Risien Russell of London, England; and that in surgery, "The Surgical Rights of the Public," by Dr. John C. Munro of Boston, Mass. "The Medical and Surgical Treatment of Gallstones, Their Scope and Relations," was the title of an instructive paper by Dr. John B. Deaver of Philadelphia. The interest in all the different meetings of sections was well maintained. The meeting next year is to be held at Winnipeg, where the newly elected president, Dr. Blanchard, resides.

The prevention of cancer in Canada is a question towards which considerable attention is now being directed, and it is proposed that an organized effort should be made to ascertain the number of patients suffering from cancer in each province. It is suggested that a struggle against cancer should be made in this country as in Germany, and that similar precautions should be taken to ascertain the extent to which the disease prevails as are now taken in regard to tuberculosis. There is no cancer hospital in Canada, but statistics indicate that there is room for at least one central institution for the special treatment of malignant diseases. From the manner in which some newspapers are openly advocating the necessity for more attention being paid to cope with the disease, public philanthropy is likely to be sufficiently stirred to provide better facilities for care of patients so afflicted.

The McGill Medical Journal Club of Montreal, which has for its object to aid the medical library of McGill University, has had a most successful year. The newly elected officers are: *President*, Dr. E. A. Archibald; *Vice-President*, Dr. A. A. Robertson; *Secretary*, Dr. A. G. Nicholls; *Treasurer*, Dr. Campbell Howard; *Executive Committee*, Drs. Morrow, Klotz and Chipman.

The fourth meeting of the Association of Physicians of the French Language for North America will meet in Quebec July 20 to 22. An excellent program has been prepared and a large attendance of French-speaking physicians and surgeons from all parts of this continent is expected. The meeting will be held a few days before the celebration of the tercentenary at Quebec, which will probably be the greatest military assembly ever held in Canada.

The necessity of having in each city regulations likely to secure a model milk supply has been dicussed at each of the medical associations in Canada this year. Several energetic and influential medical men in different sections have devoted considerable attention to this subject. The result of the present agitation is likely to result in a regulation making it necessary for any one selling milk to take out a license, and before this will be issued a certificate of the local medical inspector will be necessary showing not only that the premises are sanitary in every respect, but also that thorough cleanliness is observed at every dairy. The water supply to each dairy is to be regulated. Numerous instances have been cited where the extension of contagious diseases through the milk supply might have been prevented. Tuberculosis among cows has always to be guarded

against, but it is argued that a better plan is to have all dairies kept in a sanitary condition and to feed the cattle on food adapted to their physiological as opposed to the commercial necessities. Inspection under strict regulations will, it is urged, secure for dairy cattle unlimited supply of pure air, instead of having them shut up in ill-ventilated byres, and will prohibit feeding with brewery grains from which the wholesome elements have been removed. Pure milk requires proper feeding. The interest shown in this question in Canada at present is certain to produce results that will be of permanent and lasting benefit to the whole country.

The Vital Statistics Act of Ontario has just been amended with a view to facilitating the collection of reliable information in regard to the deaths, births, and marriages in the province. The collection of vital statistics in Ontario has hitherto been carefully supervised, but there has been a tendency in some localities to laxity in enforcing the law. In future the local registrars are to be remunerated for their work sufficiently to justify the expectation that full returns will be made. Strict regulations are now made to compel registration of every birth and death. An important amendment in the recent act states that "the removal for burial or the embalming of any body shall not take place, and an undertaker, clergyman, sexton, householder, or other person shall not engage in the burial of a body unless a certificate of registration has been previously obtained from the local registrar." The importance of this is quite evident to the medical profession.

IS THE INCREASE AND DISSEMINATION OF CANCER RELATED TO OUR MODERN WATER SUPPLY?

To the Editor of the Medical Record:

Sir:—That cancer is rapidly on the increase, comparatively speaking, at least; that this increase is more noticeable among urban people and in the rural districts immediately surrounding cities, and that this increase is alarming especially in the older cities which derive their water supply from rivers near their outlet and in those cities receiving this water supply from lakes, reservoirs, etc., where undetected contamination is constantly operative from sewerage disposal, cannot be successfully disputed. A careful investigation of mortuary statistics for the past fifty years will clearly and forcibly demonstrate the above statement. If this is true then there must be some definite cause. Careful post-mortem statistics show that one person in every ten or twelve has cancer in some form.

Cancer is probably a germ disease or originates from undeveloped cells which will begin to develop and proliferate when suitable lodgment is found. If the germs of typhoid fever, cholera, dysentery, etc., can be conveyed long distances by water and then work their destructive effects, why not those of cancer? Unlike these diseases, the cancer germ probably does not multiply outside the body. If it did and was conveyed by water then all would soon perish from the disease; but, retaining its vitality until taken into the system in drinking water, it finds lodgment and in many cases conditions suitable for development.

The washings and waste of all diseases are poured into the sewers, which discharge their contents into rivers, lakes, etc. Thus we have the avenue of pollution.

Cancer may be due to a germ that retains its vitality in water under all natural conditions. We know that fishes have cancer closely allied to if not identical with that of man. The subject is worthy of earnest consideration and careful investigation.

Terre Haute, Ind.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 2, 1908.

The Menace of the Swimming Tank.—C. M. Cobb looks upon the modern swimming tank as a menace to the integrity of the ethmoidal region and of the ear, and supports his contention by reference to several cases of ethmoiditis and acute otitis media which followed diving in the tank. It is not that the water becomes infected by other bathers and so infects a later patron of the bath, but that people insist on putting their heads under water, which is more or less dirty in spite of the attempts made to keep it clean. Mere changing of the water once or twice a day is not enough.

An Unusually Extensive Milk-Borne Outbreak of Typhoid Fever.—C. Harrington refers to an outbreak this past spring in a suburb of Boston. Upwards of 400 cases were reported in six weeks. Of 410 cases 348 primary and 23 secondary cases occurred in families supplied by two milk-route men, referred to as F. and Q. They both secured their supply from the same dairy. Investigation of the latter showed that it was all right and not the origin of the poison. Among the first of the cases reported was that of F. himself, who died of the fever, as proven by autopsy. Considering that F. had been ailing for a period of about two weeks before he took to his bed, but not to such an extent as to prevent him from handling the milk, it is not difficult to surmise in what manner the supply became contaminated with the exciting cause of the disease, for the hands of the average milkman do not receive the same degree of care as those of an operating surgeon, and with more or less frequent occasion for interrupting the work of handling the milk in order to respond to natural calls, specific contamination, first of the fingers and then of the milk, is very likely to occur. With the supply of Q, however, the connection is by no means clear. It was reported that Q received from the dairy which they had in common only those cans which F left for him after tasting all and selecting those which he wished for his own trade. This, however, is denied on apparently good authority, and, instead, it is said that on only two occasions, namely, March 15 and March 18, did F precede Q at the car. It is further stated that although each can was tasted before acceptance, those that were rejected were set aside and were not delivered to Q. However this may be, and whether or not F had an opportunity to infect the milk of Q on either of these two days or on those subsequent days, it is certain that there was the greatest possibility of an interchange of cans between F and Q, for it was the custom of each to return the cans to the car washed, but by no means sterilized; and after they were filled at the dairy and returned Q was as likely as F to receive cans which had been supplied to and handled and returned by F. Certain it is that the first infection did not occur at the place of production and was not due to the fault of the farmer; and equally certain is it that F, during two weeks of ambulant typhoid fever, had ample opportunity to infect his supply and to reinfect it again and again, and to spread the infection to Q's supply through the nonsterilized cans of the contractor which they used in common.

New York Medical Journal, July 4, 1908.

Light in the Treatment of Disease.—J. W. Kime confines his paper to a description of phototherapy as used at Boulder Lodge Sanatorium, Fort Dodge, Ia. Special attention has been paid to developing the use of the sun's rays as a therapeutic agent, particularly the blue rays. The author has constructed a condenser ten feet in diameter, focussing at a point twenty feet in front of it. An object placed in the focal point is, if combustible, immediately ignited if the white light is employed. For therapeutic purposes the rays pass through a blue glass screen before they are allowed to impinge upon the body. Concentrated sunlight penetrates through the entire thorax. As to therapeutic effects, the author does not believe that it is a mere question of killing bacteria. The short, irritating rays will increase the turgescence of an affected area, but later favorable changes are undoubtedly referable to the increased nutriment brought to the parts by the abundant flow of the capillary blood. In deep-lying tissues, capillary engorgement takes place, increased nutrition is brought to the affected areas, fibrosis is formed and reparative processes occur which might not take place under less favorable conditions. In the institution conducted by the author the condensed blue light is used in pulmonary tuberculosis, lupus, and other chronic skin lesions, and in postoperative surgical tuberculosis. In these affections light, and especially the shorter rays, is an agent of great utility. In pulmonary tuberculosis the entire chest of the patient is made bare, and the light, after passing through the blue screen, is thrown directly upon the exposed portions of the body. These rays penetrate the entire thickness of the thorax, having a retarding influence upon the growth of bacteria and engorging the parts with blood. The light is used for twenty minutes each day. Results since installing the large light have been so much better than before that there is no room for doubt as to the beneficial effect of these rays. While by no means a specific, and in the far advanced cases of but little value,

in early cases more rapid improvement is noted than was prior to the use of the light. The psychic effect of the light is an adjuvant of no small consequence in cases of pulmonary tuberculosis. If it had no other result whatever the author would under no circumstances part with its use. [An acknowledgment which greatly limits the value of his preceding conclusions as to the value of phototherapy.—Abstr.]

Another Method of Regulating Pressure in the Bier Treatment.—R. Grace suggests the use in the control of the bandage pressure in the Bier treatment of the Bishop hydrostatic manometer. This is an instrument for measuring blood-pressure by a compression caused by a column of water of varying height. It consists essentially of two rubber bags connected by a tube, one being inside of the cuff and the other arranged for elevating and depressing. In the instrument is placed about twelve ounces of water without air. An illustration shows clearly how the bandage is applied and how the pressure may be regulated by the patient. The cuff is laced to the part of the body that is to be compressed and the pressure regulated by elevating the reservoir bag. The instrument also has many advantages for measuring blood-pressure, which is indicated in millimeters of mercury on the tube and read at the level of the heart at the moment that the pulse disappears.

Treatment of Tuberculosis of the Upper Air Passages.—In a paper presented to the recent International Laryngological Congress at Vienna, J. W. Gleitsmann reports particularly on tuberculosis and lupus of the nose, pharynx, and nasopharynx. The various headings of this interesting paper are as follows: I. Tuberculosis of the nose, (1) local treatment by drugs, (2) hot-air cauterization, (3) tuberculin preparations, (4) ray therapeutics, (5) surgery. II. Tuberculosis of the nasal accessory sinuses. III. Tuberculosis of the postnasal space. IV. Tuberculosis of the pharynx. V. Lupus. VI. Conclusions. Under the final heading the author makes the following observations: Surgical interference, as well as lactic acid and the galvanic cautery, will always preserve their full value, and the latter is especially well recommended. Of the newer remedies there are the hot-air cauterization and the Finsen light, and solar rays with or without fluorescent remedies. We may expect more and better results from continued experiments from the Röntgen ray and radium. The author's best results have followed surgical operations, the galvanic cautery, parachlorphenol in intact infiltrations, lactic acid in ulcerations, and tuberculin preparations in proper cases.

Journal of the American Medical Association, July 4, 1908.

Alternating Personality.—E. E. Gaver gives the history of alternating personality showing itself in spells of wandering of which the patient was entirely amnesic in his normal state. After one of these he found himself in London, without having any idea how he got there, and passing into another, he found himself in a similar plight at the Cape of Good Hope. After that he was free from these attacks for three years, when they again returned, though not of such long duration. In the intervals he complained of more or less headache which seemed to be aggravated when his attacks came on. The details of several attacks which occurred while under observation at the hospital are narrated. The patient was easily hypnotized and then was able to give an account of his doings while in his secondary condition, of which he normally had no recollection, and after coming out from the hypnotic state he had the same tire and exhaustion as he felt after one of his periods of secondary consciousness. While hypnotized, however, he was amenable to suggestion, which was not the case in his secondary consciousness. The marked resemblance, however, of his expression, demeanor, etc., in the two conditions was noticeable, and Gaver is inclined to suspect that the hypnotic state is closely analogous to the conditions of the dissociation of the personality in this patient. The patient attributes the attacks to a sandbagging received in 1902, but is of a neuropathic predisposition and had previously suffered from nervous symptoms ("tender spine," left-sided hyperesthesia) following an attack of typhoid fever in 1898. He is still under observation and has had no disturbances of consciousness since November, 1907, but is regarded as only improved, the abulia and suggestibility remain, and a return of the dissociation of personality is considered possible.

Neurologists and Electrotherapy.—F. R. Fry says that the use of electricity in the therapeutics of neuropathic diseases does not in any instance rest on a scientific basis. The results attributed to it, he says, and the manner in which they are obtained are simply matters of opinion, always an unreliable kind of testimony, and perhaps never more so than in questions of therapeutics. Any one who has carefully used any kind of current in treatment over any considerable period, can say he has seen good and even remarkable results, but if he is any kind of a diagnostician, he must discover that many of these results are psychic in their origin, and if others are not, there is no scientific proof that such is the case. Sometimes electricity, like other suggestive measures, assists us in breaking into certain difficult psychic situations, and in that way it is often a convenience. But it is also sometimes an inconvenience in that with a large class of patients we can not induce the needed reliance on the simple hygienic measures in which they must eventually find their security, until we have entirely overcome their yearnings for therapeutic specialties. Some will doubtless continue to use electricity extensively and find satisfaction in so doing, just as some will write twice as many prescriptions as others. Our therapeutic tastes and trainings differ, but there is a general awakening to the important part played by psychic influences, and we are learning to gauge them more correctly. The present verdict of the majority of neurologists, he says, is based on a thorough trial of the therapeutic value of this agent. In conclusion, Fry mentions the diagnostic uses of electricity which are appreciated only by neurologists, or those actually capable of diagnostic refinements in neuropathic conditions. It is the only practical scientific use that has been made of electricity in medicine proper, and it is to the credit of neurologists alone, and they must also determine ultimately the therapeutic values of electricity in their particular lines of practice. Certain surgical results and some of the results of phototherapy, so called, are admitted by Fry as probable exceptions to his statement as to the generally unscientific character of electrotherapy.

Antimeningococcic Serum.—C. H. Dunn reports results of the use of the Flexner serum in 40 cases of cerebrospinal meningitis in Boston and vicinity, and summarizes his conclusions from the experience as follows: "1. The use of the Flexner antiserum is of great value in epidemic cerebrospinal meningitis. I believe its value to be comparable to that of diphtheria antitoxin in diphtheria. 2. The use of the serum at times aborts the disease, frequently rapidly relieves its symptoms, shortens its course, lessens the liability to sequelæ, and greatly reduces its mortality. 3. The serum should be used as early as possible in all cases, even of suspected epidemic meningitis. 4. It should be frequently repeated as long as there are symptoms or any tendency to relapse. 5. Late chronic cases are unfavorable for the use of the serum, but any case in which the diplococci are present has some hope of relief by its use. 6. Some cases are resistant."

Antimeningococcic Serum.—F. S. Churchill reports eleven cases treated with the Flexner antiserum for cerebrospinal meningitis, with four deaths. Two of the fatal cases, however, were not proved by bacteriologic examination to be of the meningococcic type; of the remaining two, one was a fulminant case and the other patient came under treatment in a moribund condition on the tenth day of the disease. In seven, therefore, of the nine proved cases recovery ensued. As a rule, the patients were more comfortable after an injection of the serum, but this was not always an immediate effect, and Churchill thinks that the use of an anesthetic in giving the injection might be advantageous in certain not very toxic but fairly conscious patients. A clearing up of the mental condition was the first symptom of permanent improvement in at least five cases. The temperature has shown a decided tendency to drop steadily from the beginning of the treatment, as was likewise the case with the leucocytosis and the number of the diplococci in the cerebrospinal fluid. While the number of cases is small, taken with other facts reported by Flexner and his other investigators, they show remarkable results from the use of the antiserum. Enough has already been learned to warrant its use on a large scale, and Churchill thinks it not too strong a statement to say that given a case suspected to be meningitis, it is our duty to make a lumbar puncture, and if we get a cloudy fluid, to inject the serum at once and repeat it if bacteriological examination proves the case to be one of the meningococcic variety.

The Thyroid and the Parathyroids.—H. Tuholske summarizes the accepted views as to the physiology and pathology of the thyroid and parathyroid glands, and describes a new operation for the relief of exophthalmic goiter. Following a suggestion from an experiment of Professor Guthrie of Washington University, St. Louis, who found that ligation of the thyroid veins in dogs was followed by an edematous swelling of the gland for a few days with later slight decrease in size and increased firmness of the organ and increased body-weight, he

reasoned as follows: In exophthalmic goiter we have an enlarged gland, an enormous increase in vascularity and capillary dilatation, a multiplication of the thyroid cells with abnormal activity, the presence of a great number of indifferent or vagrant cells, and a peculiar change in the thyroid gland cells—the whole condition resembling a reactive process without physiological termination. On this basis, he conceived the idea of trying ligation of the thyroid veins for the cure of exophthalmic goiter, and, after trying the experiment on several dogs, one of them goitrous, he operated in this way in a distressing and resistant case, of which he promises a future report with observations during recovery and the final late effect. Objections, he says, may be made to this procedure, which in reality consists in the production of a Bier's passive hyperemia; one of these is the greater difficulty of ligating the veins than the arteries, but this is hardly to be regarded by the experienced operator. In his case he tied both inferior and both superior thyroid veins.

The Lancet, June 27, 1908.

Dermoid Cyst Over the Mastoid.—P. M. Heath's patient, a boy of four years, had suffered from a swelling behind the left ear since birth. It had gradually increased in size and at the time of examination was half an inch in diameter. The swelling was cystic and freely movable under the skin and over the deeper structures. The cyst was removed and was found to be lined by a simple stratified epithelium and to be filled with cheesy material. There was no deficiency in the underlying bone or periosteum. The case is recorded, as dermoid cysts in this situation seem to be somewhat uncommon.

A Case of Suicidal Cut-throat.—A. B. Raffle reports the case of a miner, fifty-four years of age, who, after inflicting serious injuries on members of his own family, cut his throat with a razor and died in eight minutes (roughly) from the time of committing the act. He was a man of violent temper, who indulged intemperately in alcohol, but apparently he was sane. The wound was very severe, extending in a perfectly transverse direction across the neck to the border of the sternomastoid muscle, which was slightly divided on either side, and it divided the thyrohyoid membrane and severed both external carotid arteries just above their origin from the common carotid. The wound on section was bow-shaped, being deepest in the middle part and tapering at each end, extending down to the body of the vertebra at its deepest part. There were no wounds except the one mentioned. The case is of interest, since the wound presented more of the features of a wound that was inflicted by another than a self-inflicted wound. The man's determination was remarkable; on being caught he leveled the edge of the razor both upwards and downwards, attempting also to injure one of his captors.

Migration of the Cecum, Producing Obstruction of the Ascending Colon.—J. Bland-Sutton refers to a case of intestinal obstruction which on abdominal section revealed the following conditions: The cecum and appendix were absent from the right iliac fossa. A tense band of gut extended from the right extremity of the mesentery upwards and to the left, overlapped by mesentery and coils of small intestine; when traced upwards it led to the ileocecal junction in the left kidney pouch. A loop, consisting of the last few inches of the ileum and the ascending colon with the cecum and appendix, had been twisted on its own axis through half a circle and displayed upwards and to the left. The cecum had become adherent in its new situation and when drawn down a large necrotic area with two perforations was seen, through which liquid feces issued. The necrotic area was excised and the edges of the hole thus made in the gut were approximated with sutures. The free fluid in the abdomen was swabbed out, a large rubber tube was introduced into the pelvis, and the incision was closed with silk sutures. The man died sixteen hours after the operation. The author refers to other similar cases on record. He notes that descriptions of the condition referred to are not given in the literature of intestinal obstruction. Its importance is obvious from the fact that the majority of the patients in whom it has occurred have died. Judging from a study of the recorded cases, it would appear that the chief variations in the degree of the displacement depend upon the extent to which the twist or rotation involves the mesentery. For example, the extreme condition occurs in patients in whom the intestines, including the third part of the duodenum, the cecum, and ascending colon are attached to a common mesentery. When such an anatomical condition exists, and it is a recognized anomaly, the whole of the small intestines, the cecum, and ascending colon may be concerned in the volvulus.

Nature and Cause of Taint in Miscured Hams.—According to E. Klein, taint in hams is caused by an organism to which he gives the name of *Bacillus fœdans*. This is described in detail and its culture-figure illustrated in the paper, which also contains pictures of the affected ham tissue. The latter gives off a distinctly putrid odor, and instead of having the usual red tint is of a pale, dirty gray appearance, running on in the parts most deeply affected to a greenish hue. The tissue is swollen and of a jelly-like consistency. Under the microscope small linear clumps of tyrosin crystals are seen in the blood-vessels, in the septa dividing and subdividing the bundles of muscular fibers, and in the scant muscular tissue between the latter. The muscular striæ were wanting. Some of the fiber bundles were fibrillated, others were changed to granular matter and containing gas bubbles. All these changes indicated putrid decomposition of the proteid constituents of muscle. The litmus test gave a distinct alkaline reaction In comparing various hams thus affected, the destructive changes were most pronounced toward the knee, from which point the change evidently started. The microbe was present in the tainted parts as cylindrical rods; in the intermuscular tissue, loose connective and fat tissues, and in the tendons numerous chains and filaments of these rods occurred. In the slimy film covering the inner surfaces of all parts of the articulation the microbe was present as short or long cylindrical rods and as filaments of considerable length. Some of these filaments were merely linear series of cylindrical rods, others showed a subdivision or segmentation only here and there, so that the greater part of the filament appeared uniform and unsegmented.

British Medical Journal, June 27, 1908.

Etiology and Treatment of Eczema.—L. Kesteven regards eczema as a pure neuropathia. It is a common concurrent of many functional and nervous derangements. Even when local irritation is the exciting cause of an attack, it still remains a neurosis. For purposes of treatment cases fall into two classes: (1) Those from within acting through the sympathetic chain of the functional system, the ganglionic form, and (2) those arising from external or local irritation, the peripheral or traumatic form. There is no specific drug. Each case must be considered with reference to the causative factor. Thus, if a gouty attack has preceded, one must use the usual treatment for gout, plus a nerve sedative. Iodide and acetanilid act well here. Colchicum should be avoided, as it dilates the capillaries, tends to increase exudation, and is often irritative to the skin. If the patient is asthenic and anemic, one should give iron, quinine, and strychnine. Alcohol must be cut off. The eczema of pregnancy usually terminates with parturition. Of local applications carbolic acid, iodine, and adrenalin are, in the author's view, the only remedies of assured and permanent benefit. Of the former he says that the pure liquid acid applied to a red, inflamed eczema gives sharp but short punishment and leaves the part practically dead, and this dries rapidly, forming a scab, under which the previously raw surface heals quickly; the scab on falling off leaves the surface clean and sound. This is heroic treatment, and must be applied to only limited areas at one sitting; the pain of the application can be obviated by cocaine if the subject is sensitive, and before the effect of the cocaine has passed off the part will be anesthetized by the carbolic. For small patches, such as appear on the hands, feet, scalp and ears, it is particularly serviceable. For general use in all eczematous eruptions at every stage the 1 in 11 solution should be used, and though it certainly smarts for a time, it gives immediate relief to the symptoms and rapidly checks and arrests the progress of the eruption. Tincture of iodine also smarts somewhat, but gives great relief to the itching and burning and lessens the infiltration. The two together make a happy combination—℥j of tinct. iodi. to ℥ix of the 1 in 11 carbolic solution for a lotion, to be kept applied on lint under oiled silk. In the intertrigo which so commonly occurs between the toes and extends into the tough skin of the feet, a bath of this for the feet, frequently repeated, gives wonderful relief. Starch poultice makes a good vehicle for the application of this lotion and is useful on tender surfaces such as the face and neck. Suprarenal extract is a good application previous to the carbolic, owing to its power of reducing the turgescence and exudation, thus leaving the surface fit for its action, while, applied in the very beginning of the initial erythematous stage,

it will often entirely arrest it. Adrenalin is undoubtedly the best form of this substance.

Cerebral Influenza.—Cases of this affection are reported by T. G. Moorhead, T. W. Clay, and J. Livingston. The symptoms variously observed were general weakness, rise of temperature, inability to stand or walk, vomiting, violent head pains, delirium, coma, paresis, convulsive seizures, etc. Of the four cases reported, three recovered and one died. It was difficult to make a positive diagnosis at the outset, except that it was evident that the patients were suffering from some profound toxemia of the nervous system. No special treatment was employed beyond the meeting of the various symptomatic indications. The general type of the severer cases was not unlike that of a cerebrospinal meningitis.

Berliner klinische Wochenschrift, June 22, 1908.

Experimental Glycosuria.—Eichler and Silbergleit tell of Zack's observation, that glycosuria may appear after injury of the duodenum by caustics. Pflüger produced diabetes in the frog by extirpating the duodenum without interfering with the pancreas, or even simply by cutting the nerves which pass from the pancreas to the duodenum. The authors experimented with dogs, destroying the mucosa of the duodenum by the application of caustics and, in some cases, by the use of the Paquelin cautery. Sugar appeared in the urine of the animals after the operation; no prolonged diabetes could be produced, and control experiments with the destruction of the mucous membrane elsewhere in the bowel showed that the same phenomenon may result in some cases. The authors think that hepatogenic glycosuria is produced by the operation, the intense irritation of the mucosa of the intestines being accompanied by a like effect upon the liver. The latter organ, accordingly, begins to excrete glycogen very rapidly, and thus leads to the appearance of sugar in the urine. The technique of the operation is very simple, and the animals stand the procedure very well. The method may therefore be used for the production of glycosuria for the purposes of research.

Dislocations of the Hip in Little's Disease.—Wollenberg says that dislocation at the hip is a frequent accompaniment of Little's disease in children. Of ten successive cases examined by him three showed the presence of complete dislocation, and a fourth a marked tendency toward its production. One patient had a bilateral dislocation. Wollenberg thinks that the complication should be prevented by early interference with the existing muscle spasms by means of myotomy of the adductors and the flexors of the hip. If necessary, further tenotomies are to be performed, the limb being placed in extreme adduction, and fixed by plaster bandages or by splints, this attitude keeping the head of the femur in the deepest part of the acetabular cavity. Existing dislocations ought to be reduced though recurrence of the condition is frequent.

Munchener medizinische Wochenschrift, June 23, 1908.

Cutaneous Reaction with Fat-free Tuberculin.—Leber and Steinharter say that v. Pirquet's cuti-reaction for tuberculosis is only of value in early childhood, most of the adults giving a positive reaction to the test in spite of absence of any tuberculous lesions; the ophthalmoreaction, on the other hand, is too dangerous to be used except in occasional cases. They have experimented with a fat-free preparation of tuberculin and find that the results of the cutaneous test with it are much more valuable. Sixty patients out of seventy in the first stage of tuberculosis, thirty-nine out of forty-seven in the second stage, and seventeen out of fifty-eight in the third stage reacted positively with the new preparation. One hundred and forty-eight out of one hundred and fifty-two patients suffering from other diseases, *i.e.* 97.3 per cent., gave a negative reaction. The authors give in detail their technique of preparing fat-free tuberculin, and recommend its use to enhance the value of the cutaneous reaction.

Total Resection of the Sternum.—Siegel has found only seven cases of this operation reported in the literature. The most frequent indication for the operation has been tuberculosis, then follow tumors of the sternum and of the mediastinum, while partial resections are quite frequently performed in preparation for surgical treatment of the lesions of the heart and of the great vessels. Siegel thinks that the operation ought to be performed more frequently, especially if the posterior wall of the bone is involved by tuberculosis, in which case curetting of the focus of disease is seldom of much use. He communicates the particulars of a case in which total resection of the sternum was performed and a coexisting tuberculous cavity was opened at the same time. The result was favorable, the cavity being healed completely with the help of artificial hyperemia.

Deutsche medizinische Wochenschrift, June 18, 1908.

Vaginal Operation in Tubal Pregnancy.—Dührssen says that the vaginal extirpation of the pregnant tube is in many cases preferable to the usual "ventral" operation. The surgeon, however, must have mastered the technique of colpoceliotomy and its special application in removing the inflamed or otherwise diseased adnexa, and must have the assistance of two men in addition to the anesthesist, and a well equipped operating-room. If these conditions are present, the extirpation of the tube by anterior colpoceliotomy is indicated in the first three months of tubal pregnancy in the following cases: If the tube is not ruptured; if rupture has taken place and free blood is present in the peritoneal cavity, yet the condition of the patient is such that time may be taken for properly preparing her for the operation; if tubal mole exists with or without peritubal hematoma. In cases of large or old hematoceles simple drainage by opening them through the posterior vaginal wall is indicated; if there is danger of secondary hemorrhage, the "ventral" operation with the removal of the gravid tube is to be preferred.

Secretions of the Suprarenals in the Blood and Urine.—Waterman and Boddaert say that the presence of adrenalin in the blood and urine of nephritics is not at all proven. Both the color reaction with iron chloride solution, greenish-blue color, which becomes pink on warming, or on addition of potassium hydroxide, and the dilatation of the pupil in the extirpated eye of a frog do not prove its presence, but simply give evidence of increase in the amount of benzcatechin derivatives in the blood of such patients. Before making any conclusions as to the rôle of adrenal products in nephritis a good test for the substance must be found. At present it can only be said that the blood serum and the urine of nephritics contain more mydriatic substances than the like fluids of healthy individuals.

French and Italian Journals.

Mixed Tumors of the Uterus.—P. Peuch and G. Massabuau describe mixed tumors of the uterus as occurring like hydatid moles, hanging in the vagina with a pedicle reaching up into the uterus. They consist for the most part of connective tissue, fibrous, myxomatous, sarcomatous, and adipose tissue, and unstriped muscular fibers, all of which are related to the tissues of the organ. There are two heterogeneous tissues found in them, striped muscle and cartilage, which is generally hyaline and found in patches. The symptoms are hemorrhage, leucorrhea, and pain, with sense of weight. The best theory to account for their existence is that they are embryomas, since from some part of the urogenital canal any one of these tissues may develop. The evolution of these tumors is like the malignant growths. They end in death from cachexia when left to themselves. When removed they recur easily and quickly and may give rise to metastases at a distance. Operation, to be successful, must be complete, abdominal hysterectomy being preferred.—*Gazette de Gynecologie*, May 15, 1908.

Chronic Appendicitis in Children.—J. Comby finds that appendicitis in children is comparatively frequent, and is essentially a chronic disease which may have existed for a long time with insignificant and vague symptoms before the acute attack caused a diagnosis to be made. It occurs in well nourished children who have a hereditary predisposition to the disease, and in cachectic children who have been subject to intestinal and gastric troubles all their lives. Another class of patients is that in which adenoids, tonsillitis, and nasal troubles, with enlargements of the cervical glands are frequent. It is frequently associated with cyclic vomiting and mucomembranous colitis. The chief symptoms are indigestion, lack of appetite, pains in the abdomen, and constipation. Intestinal catarrh may exist instead. Infectious diseases are very apt to cause attacks of appendicitis. The differential diagnosis has to be made from enterocolitis, hepatic and renal colic, movable kidney, and dysmenorrhea and ovarian troubles in young girls. Many surgeons claim that an operation in the interval is demanded in all cases. For the milder cases rest, attention to the diet, and to the bowels is in order, as some cases become cured by sclerotic changes.—*Le Bulletin Médical*, June 10, 1908.

Corrosive Sublimate Applied Without Pain.—Appleman (*American Medicine*) states that when solutions of mercuric bichloride are made with normal salt solution instead of water, they do not cause the slightest pain when applied to the mucous membranes.

Book Reviews.

The Common Sense of the Milk Question. By John Spargo, Author of "The Bitter Cry of the Children," etc. New York: The Macmillan Company, 1908.

Mr. Spargo's book is an attempt to acquaint the general reader with the problem of the relation of the public milk supply to the public health. He very properly says that there are no mysteries in this problem that are beyond the comprehension of an intelligent layman; a thorough acquaintance, on the other hand, with the questions and difficulties involved is the best preparation for an intelligent attitude in the matter. As an introduction to the main body of the work, Mr. Spargo writes of "The rise in the value of babies" which has taken place with the course of time, and of the reasons for the failure of many mothers to provide the natural and best food for their infants, namely breast milk. Cow's milk as the best substitute is then considered and the various and devious ways in which this article of food suffers deterioration and adulteration while on the way from the cow's udder to the baby's mouth are fully presented. The summary of the problem is then stated, its expression being found in a few phrases: dirty milk, high infant mortality as a consequence, the great economic and political difficulties in the path of improving the situation. As a remedy for the evils Mr. Spargo proposes many far-reaching measures, among them the establishment of a "National Milk Reform Association"; rigid enforcement of certain standards of cleanliness and purity; infants' milk depots; the elimination of tuberculosis from the dairy herds; the education of mothers in the principles of milk hygiene, etc. This brief summary of the book's contents show that it is of interest both to the general reader and to the physician, who, above all, ought to have an intelligent opinion in the matters discussed.

The Every-Day Diseases of Children and Their Rational Treatment. By George H. Chandler, M.D. Chicago: The Clinic Publishing Co., 1907.

To those who are interested in the subject, this book may be welcomed as a practical expression of the efficacy of alkaloidal therapeutics in the treatment of the diseases of children. The arrangement and classification of the text are practically the same as in other works on pediatrics. Very little space is given to a consideration of diagnosis and prognosis, most of the work being devoted to therapeutics, especially to alkaloidal treatment. Like most members of this school of therapeutics, the author is a firm believer in the power of drugs to curtail disease. In speaking of the treatment of varicella, a disease which is self-limited, and whose treatment is simply symptomatic, the author, after advising the administration of a cathartic, says: "Calcium sulphide and arsenic sulphide are the two main remedies; the administration of gr. 1/3 of calcium sulphide every two hours and gr. 1/67 of arsenic sulphide after each meal checking the disease within four days. The papules cease to appear, the few vesicles shrink and rapidly dry up, and normal conditions are reestablished."

Diagnóstico y Tratamiento de las Enfermedades de las Vías Urinarias, por Alberto Suárez de Mendoza, Professor de Enfermedades de las Vias Urinarias en la Facultad de Medicina de Madrid. Madrid: Perlado, Páez y Ca., 1908.

Although his book is modestly offered as "elementary lessons," Professor Suárez de Mendoza covers the field of genitourinary diseases as exhaustively as is possible in 778 large quarto pages and 12 pages of an excellently made index. The general plan of the book follows that of Guyon's Maladies des Voies Urinaires, without, however, for that reason lacking in originality of presentation. As is proper in a text-book for medical students and junior practitioners, the author avoids polemics and consequently omits, without doing violence to facts as he observes them, minor points, such as for instance, the discussion of priority in methods, instruments, etc. It is therefore readily comprehensible that the author attributes a discarded form of the Valentine urethroscope to Luys. Suárez de Mendoza's attitude regarding the treatment of gonorrhea by irrigations is shown (p. 277) as follows: "Tens of thousands of patients in Spain have been treated and cured by this method. None other is employed in the San Juan de Dios where it was introduced ten years ago by Professor Sanz Bombin." The author most profitably and interestingly emphasizes the genitourinary conditions that may simulate other diseases, such as intermittent fever, gastroenterological conditions from dyspepsia to most obstinate constipation or diarrhea, joint diseases, neuralgias, rheumatism, etc. He shows, by most fascinatingly related histories, how readily they subside, as the genitourinary affection is relieved. The second to the seventh lessons of this work are devoted essentially to disturbances in urination and their pathological significance. The forcefulness of his presentations are well demonstrated by lines which he emphasizes as follows: "When pollakiuria evinces itself as intensely at night as it does during the day, the existence of pyelonephritis must be sought" (p. 17), "....as Heister said, 'in case of retention there is no choice except to urinate or die'" (p. 21). In the treatment of urinary incontinence of children that has resisted the usual methods (p. 35) Suárez de Mendoza enthusiastically endorses Cathélin's epidural injections (fully detailed in the Medical Record, September 26, 1903). In his study of anuria the author relates the case of a woman whom he successfully operated upon on the tenth day of suppression. He further recites that hysterical anuria may last fifteen days and more without danger. He warns the student, however, that persistent apyretic anuria presages death. The author's differentiations of the hematurias are most clearly presented. As an aid to urethral irrigations Suárez de Mendoza offers a double cannula, destined to avoid penetration of solutions into the bladder. He also describes a sterilizer for catheters and bougies, devised by him, that acts as a case for these instruments as well. It is singular that our author, striving to "render unto Cæsar," neglects to give Piffard credit for his small but important meatometer, which he describes and illustrates without mentioning its originator. It is regrettable that the space which can be allowed so generally admirable a work prohibits consideration of the parts devoted to major genitourinary surgery. The hope is justifiable that this important work will find a translator for the benefit of those who do not read Spanish.

Nursing the Insane. By Clara Barrus, M.D., Woman Assistant Physician in the Middletown State Homeopathic Hospital, Middletown, N. Y. New York: The Macmillan Company, 1908.

Published in April, 1908, this is one of the latest books on nursing the insane. It is also one of the most complete. The asylum woman physician comes into close contact with both the attendant and the insane patient; and, at the beginning, her services were utilized, perhaps, more as a head trained nurse than as a physician. This early enforced experience has been of service to both physician and attendant, in many ways, and reacted to the benefit of the patient. An intimate knowledge of practical necessities in nursing and care of the insane seems to be reflected in this book; and from it the asylum nurse may gain many valuable practical suggestions both in regard to nursing and management of the insane, and to the more common medical and surgical conditions arising in any community; but she may also obtain considerable information respecting the insanity laws and customs of New York State. We are glad to note that but little space is devoted to psychology. Many useful hints are given in the moral (or mental) treatment of the insane. There are no chapters on anatomy or physiology. Theory, in fact, gives way to practice throughout the book. Homeopathic practice, *per se*, does not obtrude itself.

Practice of Medicine for Nurses. A Text-book for Nurses and Students of Domestic Science, and a Handbook for all those who care for the sick. By George Howard Hoxie, A.M., M.D., Professor of Internal Medicine in the University of Kansas; Superintendent of the Eleanor Taylor Bell Memorial Hospital, Kansas City. With a Chapter on the Technique of Nursing by Pearl L. Laptad, Principal of the Training School for Nurses of the University of Kansas. Philadelphia and London: W. B. Saunders Company, 1908.

The literature of nursing is increasing rapidly. Text-books are appearing on every branch of medicine and surgery, devoted to the needs (or supposed needs) of nurses. The present volume is on the Practice of Medicine, and covers the ground quite satisfactorily. But occasionally material is introduced which cannot in any way concern the nurse. For example, in the chapter on Malaria, we find: "The diagnosis of malaria, therefore, depends on finding these organisms in the blood; and without such finding a diagnosis of malaria is simply guess-work. It is necessary, therefore, for any physician who would diagnose malaria to have access to a high-power microscope, and be able to use the modern methods of staining the blood for examination." Again, in the same chapter: "We would reiterate the necessity of using a microscope to determine whether or not the patient ill with chills and fever has really malaria." Diagnosis is not within the province of the nurse. There is a useful chapter on the care of the patient and the sickroom, by a nurse (Pearl L. Laptad). The book contains much that will be of service to those for whom it was written.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held April 16, 1908.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

The Pathological Changes in the Thyroid Gland as Related to the Varying Symptoms in Graves' Disease, Based on the Pathological Findings in 275 Cases of Exophthalmic Goiter.—Dr. LOUIS B. WILSON of Rochester, Minn., read this paper, illustrating it with lantern slide projections and stereoscopic views. The material for his paper was obtained from operations and autopsies on cases of hyperthyroidism (exophthalmic goiter) in St. Mary's Hospital, Rochester, Minn. All specimens were brought immediately from the operating room to the laboratory, usually within ten minutes after they were removed, and examined fresh and then placed in fixatives. The histology of each case was carefully reviewed from all the preparations at hand, and notes made according to a formula compiled from the reports of previous observers. While this review was in progress every care was taken to exclude all knowledge of the clinical histories of the cases in order that there might be no clinical bias entering into the pathological estimate. As the work progressed it was found that certain pathological pictures were repeating themselves with monotonous frequency. When the examinations were completed these pictures were found to present cases forming four large natural groups, and there was little trouble in arranging the remainder of the cases so as to form connecting groups between the large and more striking ones. On the basis of this grouping, which was from the study of the sepcimens alone, and on the working hypothesis that Graves' symptoms arose from increased absorption of thyroid secretion, Dr. Wilson ventured to make a conjecture of the probable clinical history of each case. This was an attempt to determine in as unbiased a manner as possible, whether or not there existed any definite relationship between the varying pathological changes in the thyroid gland and the varying symptoms in Graves' disease. The cases were grouped from a pathological standpoint into two series: Series 1, those showing marked increase of the total number of parenchyma cells within given alveoli, and these were divided into four groups, according to the development of the process. Series 2, those showing an increased number of alveoli only without extra alveolar increase, and these were divided into four parallel groups in a similar manner. Dr. Wilson said that, while their cases were too few to draw positive conclusions, yet so far as they went, one would seem to be warranted in making the following tentative statements, from the clinical standpoint:

1. Very early acute cases showed pathologically hyperemia and cellular hyperplasia, if not throughout the gland, at least in much of it, provided, of course, the more enlarged lobe had been removed.

2. Later acute, moderate, severe, and very severe cases showed greater parenchyma increase, and in many instances evidence of increased absorbable secretion. Speaking broadly, the parenchyma increase was in direct proportion to the intensity of the symptoms. The relatively few variations from the rule might be accounted for by the varying resisting power of different individuals. Where relatively small amounts of absorbable secretion were found in alveoli whose walls were crowded with actively functionating cells, they must assume that the secretion had already been absorbed. In fact it would seem a necessary conclusion that in any gland with a given amount of secreting parenchyma, the less secretion found in its alveoli at any given moment, the greater the amount that had been absorbed. In regard to the secretion, both the histologist and the chemist were measuring only the complement of that portion which had been absorbed, and which was directly responsible for the symptoms.

3. Cases in which clinically there was any remission of toxic symptoms, showed somewhere within the gland more or less evidence of decreased function in the exfoliation or flattening of parenchyma cells, or of decreased absorption, by the presence of thick gelatinous stainable secretion, so-called "colloid."

4. Cases which have recovered from their toxic symptoms, and were now principally suffering from long previously acquired heart or nerve lesions showed exfoliated or flattened, nonsecreting epithelium and large quantities of well-stained thick gelatinous nonabsorbable colloid. In this class of cases it would seem as futile to search for previous causative parenchyma increase as to look for diphtheria membrane in the throat of a patient suffering from postdiphtheritic paralysis. As for the thick gelatinous colloid itself, it was difficult to conceive of its ever being absorbable, but that, even in the thyroids of healthy individuals, it was but the retained complement, degenerated probably, or the absorbed portion of the secretion. Its presence in large amounts in any thyroid would seem to bear a similar relation to secretion and excretion by the gland, as the retained urine in a hydronephrosis did to secretion and excretion by the urinary apparatus.

5. The recently developed very mild or the moderately mild cases of long standing were almost always pathologically adenomata, in which, while there was some total parenchyma increase by the multiplication of alveoli, there was not greatly increased functionating power of the individual parenchyma cells. Goiter of the adenoma type apparently passed through the same changes of hypertrophy and degeneration as those of the adenopapilloma type.

6. Simple goiter should be regarded as multiple retention cysts filled with nonabsorbable secretion, cell detritus, etc.

The Surgical Aspects of Exophthalmic Goiter.—Dr. WILLIAM S. HALSTED of Baltimore recalled some experiments on dogs in producing hypertrophy of the thyroid gland, and gave a blackboard demonstration of what took place in the dog's thyroid. The dog might present the typical gland of exophthalmic goiter, and yet give no evidences of the disease. It was a very difficult matter to interpret in every case precisely what the clinical symptoms would be. He agreed in the main with all that Dr. Wilson had said. A patient might present himself with quite a large parenchymatous goiter which did not present the gross lobulations that appeared in the colloid variety. There might be slight exophthalmic symptoms, but no exophthalmos; again, there might be nervousness, tachycardia, and large goiter. Although this was not a colloid goiter in the ordinary sense of the word, still the patients would state that the symptoms began with the appearance of the goiter. Such a goiter was not what was generally understood as Basedow's. There were various forms of goiter. There was one form which grew quite large—almost as large as the largest Dr. Wilson showed—and yet presenting mild symptoms. This was not the pure type of exophthalmic goiter. It was interesing to note that one might meet with an exophthalmic goiter which had been engrafted upon an ordinary colloid goiter; and then the reverse might obtain. With regard to operation, it might be a partial one, such as the ligation of the arteries, or the removal of portions of the gland or lobe; or one might do a lobectomy, or excision of one lobe. In this latter operation one should be careful not to injure the parathyroids or the circulation. To avoid injuring the parathyroids the subscapular operation was to be preferred with some modifications. The operation should be as bloodless as possible. The inferior or recurrent laryngeal nerve should not be injured, nor should it be caught in the ligature. Dr. Halsted preferred

using catgut ligature because, if this nerve was caught, it would be liberated when the catgut was absorbed, and so have its function restored. Transplantation of the parathyroids could now be done, and with success. As a result of the work done in Baltimore, he thought they were justified in placing the parathyroids back in the same human being; but whether we were justified in asking another human to give up the parathyroid, with or without moneyed consideration, he said he was not now prepared to say. Last winter he found a man who was willing to give up his parathyroids. This man was to be operated on because of a tumor, a lymphangioma of the neck. The tumor was removed, and then, to their surprise, as well as their keen disappointment, they found no parathyroid, only a small projection at the angle of the jugular and subclavian veins. Never before in animal or man had they failed to locate the parathyroids. Dr. Halsted then gave a blackboard demonstration of the method of transplanting the parathyroids. If one included Basedow's disease, adenoma, cysts with symptoms of exophthalmic goiter, there were probably in Baltimore 170 cases, all told, of exophthalmic goiter. Until last winter they had had but one death as the result of the operation for exophthalmic goiter. They had cured a very few cases, and probably had as many as four or five perfect cures. As a rule, the results of the operation for exophthalmic goiter were good, and many patients had been enabled to return to their usual avocations.

Some Considerations of Exophthalmic Goiter from the Medical Standpoint.—Dr. Alfred Stengel of Philadelphia read this paper. He said that if practitioners were able to have the gland removed in every case it would be easier to reach reliable conclusions as to the pathology in all varieties of this disease than had thus far been possible. The present day views of the pathological anatomy of this disease were based upon studies of glands obtained from cases of more or less abnormal character, with established and long-standing changes in the structure of the thyroid. There were cases in which goiter occurred with symptoms of hyperthyroidism, in which recovery, either spontaneous or under treatment, might occur within a short time. When the symptoms were pronounced, one was not in much doubt as to the propriety of calling the disease Graves' disease, but when there was only moderate enlargement of the gland, and the evidences of hyperthyroidism were but ill-developed, great difficulty was encountered in making a diagnosis. Temporary enlargement of the thyroid gland was known to occur from very trivial causes, such as menstruation, pregnancy, and emotional conditions. One could not escape the conviction that in many of these cases the enlargement was simple congestion. There were other conditions in which there was more persistent enlargement of the gland without marked functional effects. Among these conditions anemia, especially chlorosis, circulatory disorders, and nervous conditions were notable. (1) Anemia.—If one examined a series of cases in advanced chlorosis, enlargement of the thyroid would be encountered in a large proportion. There might also be tremor, palpitation, rapidity of the heart action, fullness of the eyes, etc., and yet these symptoms might be nothing else than the result of the anemia. In some cases the symptoms were so marked that one could not avoid the conclusion that they were the result of hyperthyroidism. The difference between these two groups might be one of degree only. (2) Circulatory Disorders.—In mitral disease and in some other forms of cardiac hyposystole with venous congestion some enlargement of the thyroid gland was not infrequent. Two groups of cases might be distinguished here also. A large class in which symptoms of hyperthyroidism were not demonstrable though cardiac irregularity and rapidity, tremors, sweating, and even fullness in the eyes might be present as the result of the circulatory derangement. In the second group, pronounced symptoms of hyperthyroidism appeared. (3) Nervous Conditions.—Emotional disturbances were known to occasion some enlargement of the thyroid gland in certain persons. The symptoms of fear in many respects bore a resemblance to Graves' disease; medical literature contained a number of instances of acute Graves' disease resulting from fright, and terminating in rapid death, or in a chronic form of the disease. The mode of termination might be significant of the different grades of severity of the disorder of the thyroid gland and of the whole organism, or of different degrees of resistance. Spontaneous cure or rapid recovery under ordinary treatment was evidence of the nonexistence of any serious lesion. In clinical experience, difficulty might arise in reaching a conclusion as to the significance of thyroid enlargement and the associated symptoms in organic as well as functional nervous states. He recalled a recent case of dementia præcox in which there was distinct thyroid enlargement and some suggestive symptoms of Graves' disease. He also spoke of a case of Landry's paralysis in which symptoms of Graves' disease preceded the final development of symptoms and death. Such cases made it difficult to escape the conviction that the thyroidal phenomena were merely secondary, and not to be interpreted as acute Graves' disease. The discussion of these doubtful cases was important for the following reasons: (1) Because some patients with temporary and mild hyperthyroidism recovered spontaneously. (2) Because in estimating the seriousness of the disease and its amenability to treatment such mild cases should be taken into account. (3) Because in attempting a classification that would be of use in directing proper treatment these cases should be distinguished from cases of true Graves' disease. Much difference of opinion existed among the profession as to the curability of the disease, and this was in all probability due to the fact that some included these doubtful cases and others did not. Statistics gave little light upon the subject. The truest estimation of the seriousness of the disease might be obtained by determining the frequency of recovery. Ord and Mackenzie stated that in about 50 per cent. of the cases complete recovery would eventually take place. No such flattering statistics could be made if one took only the cases of Graves' disease seen in the hospital wards. The question as to what data could be depended upon in distinguishing between the milder cases of hyperthyroidism and Graves' disease proper might be answered by saying that the character of the thyroid enlargement and the other clinical manifestations be considered and that the associated diseases, such as anema, circulatory disorders, nervous conditions, and antecedent history be taken into account. In regard to previous history, he said that many instances of Graves' disease possibly had their origin in the milder conditions alluded to, which had been allowed to remain uncorrected, and also to various acute infections. The importance of referring to these cases was that the thyroid condition might readily be overlooked, and he thought the alert clinician should detect thyroid diseases in their incipiency and correct them. Dr. Stengel then referred to symptoms that were less commonly discussed, such as the occurrence of lymphocytosis and the condition of the blood. His personal experience was that not much reliance could be placed upon the occurrence of lymphocytosis. In some cases enlargement of the lymphatic glands in the neck was met with, but his experience would not justify him in placing any reliance upon this as a diagnostic point. He could not place any reliance upon the enlargement of the thymus gland, although this condition was of regular occurrence. General adynamia and gastrointestinal symptoms were generally of more importance than was supposed. In doubtful cases these points might aid in making a diagnosis. Palpitation of the heart and tremor occurred so often in other conditions that their diagnostic value was not very great. Clinicians recognized that

Graves' disease was secondary to other thyroid diseases. The practitioner had to deal with three important types of Graves' disease: (1) Cases of moderate enlargement of the thyroid gland with mild symptoms of hyperthyroidism, occurring in either constitutional, circulatory, or nervous conditions, and which usually got well. (2) Typical cases of hyperthyroidism associated with fixed organic changes in the thyroid gland. These were cases of classical Graves' disease, and recovery might, or might not, result from proper medical or surgical treatment. (3) Cases of long standing goiter or other thyroidal diseases in which symptoms of Graves' disease supervened. Such cases belonged to the domain of surgery.

Stated Meeting, Held May 7, 1908.

The Gibbs Memorial Prize.—The Committee on the Edward N. Gibbs Memorial Prize announced that it would not award the prize this year. At the suggestion of the Committee, the Board of Trustees made a gift of $500 for the essay by Dr. Norman E. Ditman of New York City.

An Old and Valuable Gift.—A mortar and pestle were offered and accepted by the Academy. They had been used by Dr. Daniel Whitehead Kissam, who was born at Manhasset, Long Island, March 23, 1763. He graduated from the University at Oxford, and his medical education was under the supervision of Dr. Richard Bayley.

Lack of Accommodation for the Advanced Tuberculous Patients.—Dr. L. R. Williams, Chairman of the Section on Public Health, under whose auspices this meeting was held, said that at a meeting of the Section on Public Health, held on April 14, 1908, Robert W. Hebberd, Commissioner of Charities, spoke very forcibly of the overcrowding existing in institutions for tuberculous cases under the care of the Department of Public Charities. In 1905 there were admitted to the Metropolitan Hospital Tuberculosis Infirmary, 2,929 patients; in 1906, 2,531; in 1907, 2,798; the highest number during these three years, 1905, 1906, and 1907, was 640 on November 20, 1907. The greatest number of patients in the hospital at any one time during the present year was 801 on March 26. These figures were for a building meant to accommodate not over 680 patients, in a building originally erected for the care of the insane. In March, 1908, 121 patients slept on the floor. Commissioner Hebberd spoke of the possibility of removing the workhouse from Blackwell's Island and having it made available for tuberculous patients. In the discussion Dr. Alfred Meyer told of a waiting list of 41 at Montefiore Home and of 25 at the Bedford Sanitarium. Dr. Cauldwell and Dr. Shively spoke of the overcrowding at St. Joseph's Hospital. Dr. Frissell spoke of the overcrowding at Seton and Dr. Miller of the continuous number of applicants for the tuberculosis ward at Bellevue Hospital. Dr. Billings had since reported that there were 144 patients on the waiting list for Riverside and 74 names on the waiting list for Otisville. With these facts in mind, the Section on Public Health passed the following resolution:

"Realizing the fact that the total number of tuberculosis cases in this city is steadily increasing and that there has been no marked increase in the number of beds for tuberculous cases, and that the overcrowding now existing in several institutions in this city is a wrong to the sick poor, as well as a disgrace to the community.

"Be it resolved, that the Section on Public Health respectfully request the Council of the Academy of Medicine to bring this matter before the next meeting of the Academy of Medicine."

This resolution was substantiated by the fact that in 1900 there were 11,927 cases of tuberculosis reported in Greater New York, with 8,154 deaths, and in 1907 there were 19,725 reported, with 8,199 deaths. In consideration of the above facts the following was voted:

"Be it resolved that the Academy of Medicine deplore this great lack of accommodation for advanced tuberculosis cases in this city and earnestly request the Board of Estimate and Apportionment to take the proper steps to relieve this immediate need.

"Be it further resolved, that a copy of the above statement of facts, with this resolution, be sent to the Mayor, Comptroller, and President of the Board of Aldermen."

These resolutions took the usual course.

Possible Sources of Typhoid Fever in New York City.—Dr. Walter Bensel, Sanitary Superintendent of the City of New York, read this paper, which was followed by lantern slide pictures. He said that for some years the Department of Health, through its inspectors, had been making investigations into the possible sources of infection in each case of typhoid fever reported to the department, and the further they went the more were they impressed with the utter unreliability of any statistics based upon such investigations. In 1907, in the City of New York, there were reported 4,076 cases of typhoid fever. Of these the result of the investigation would seem to show that 663 were due to contaminated drinking water, 576 to contaminated milk, 113 to contaminated oysters, 294 to direct exposure to other cases, 866 contracted the disease out of town, and in 1,564 the source of the infection was not even open to surmise. He said he wished it to be understood that his remarks were in no sense a criticism of the department in making the investigations. There could be no question that typhoid fever could be caused only by the entrance of typhoid bacilli into the mouths of non-immune persons. The point for the sanitarian therefore was that the prevention of typhoid lay in the disinfection of infected excretions and materials from cases of typhoid, and in the protection of food and water supplies from contamination by excreta. The most striking evidence that typhoid was largely spread by contaminated drinking water was shown by the fact that in any community the death rate from typhoid declined in direct proportion to the introduction of proper protection of the water supply. In Massachusetts, since 1901, 90 per cent. of the inhabitants had been supplied by water under public control, an amount of protection provided by no other State in the Union. The water supply of New York City was most complex: the Croton watershed for Manhattan and the Bronx, the Bryan watershed and the product of a private company, together with some private wells, for the Bronx; the Ridgewood system, New Utrecht, and Gravesend stations, belonging to the city, and eight private water companies and other private wells supplied the Borough of Brooklyn; the Long Island City, Flushing, College Point, and Whitestone plants, together with five private companies and numberless private wells, supplied the Borough of Queens; the Municipal plant at Tottenville, and two private water companies, together with many private wells, supplied the Borough of Richmond. Constant supervision of all these various sources was maintained by the Department of Water Supply and the Department of Health, both by analyses and by inspection, and many instances of pollution had been found and eradicated. He then recalled some interesting facts regarding the outbreak of typhoid in the town of Katonah, as well as in the town of Plymouth, Pa. In the latter outbreak, in 1885, a single case of typhoid fever occurring on the watershed resulted in thirty days in 1,100 cases among a population of 8,000. Instances of this kind had been numerous, and showed how readily typhoid might be spread by means of a contaminated water supply. To show how necessary it was to investigate very thoroughly before assuming that milk was the carrier of infection, the outbreak of typhoid fever in the Borough of Brooklyn, in the year 1905, might be cited. Investigation of 941 of these cases showed that in 244, or 38.7 per cent., the milk supply came from one large company. Further investigation was necessary to show

that this same company supplied milk to a very large number of persons all over the City of New York, and that in other boroughs of the city the proportion of cases occurring among their patrons was only 7 per cent. Still further, it was found that this company actually supplied about 75 per cent. of the total amount of milk consumed in Brooklyn. It seemed reasonable to believe, therefore, that the milk had absolutely nothing to do with infection in these cases. Many instances have been found of oyster beds in polluted waters and much evidence was shown that the oysters were "fattened" in badly polluted streams. Every dealer now had to state the source from which he obtained the oysters and during this coming summer investigations would be made of these sources, and wherever there seemed to be danger through pollution of the water in which the oysters were grown, or through pollution of the waters where the oysters were freshened or fattened, the dealer would be compelled to discontinue that particular source of his product or his permit would be revoked and he would not be permitted to carry on his business in the city. While it was without doubt a fact that many oyster beds could be found in polluted waters of New York City that contained sewage contamination, it was also a fact that 90 per cent. of the total of oysters used in New York for food purposes came from points outside of those from which all the tests were made. He said there could be no question concerning the danger of possible contamination of oysters, but that such contamination was widespread might be seriously doubted. Green vegetables, if washed in polluted water, might be a source of typhoid fever, but such cases were very few. Contaminated water, whether taken in as drinking water, or possibly contaminating in its turn milk or fresh vegetables, seemed to be the main carrier of typhoid. Constant inspection and supervision of New York City's water supply could not possibly reduce the danger of such contamination to a minimum. In addition to inspection, filtration of the whole city's water supply was undoubtedly essential.

Dr. E. G. Janeway said that he was a member of the committee appointed to investigate the source of water supply to this city, and saw conditions similar to those described by Dr. Bensel. He went to Albany and pointed out the existence of these conditions, but no good resulted from the information he gave the members of the Legislature. The Deaf and Dumb Asylum had many outbreaks of typhoid fever, and in 1868 Professor Metcalf asked him to investigate 60 or 70 cases. Dr. Janeway found that there were half a dozen cases of pure typhoid, and the others had aborted. In other words, there were two kinds of typhoid; one the ordinary typhoid fever as they knew it; the other, a typhoid that ran a course of from three to ten days, and then ceased. The Board of Health investigated this and the question arose, where did it come from? Steps were taken to improve the sewage and drainage. The next outbreak in this institution was found to be due to an eroded vent pipe. When Dr. Janeway was Commissioner of Health there occurred another outbreak, and this time the disease was very limited. The source of contamination was found to be from an infected well. Five hundred feet from the hospital was the only pump there. The drain pipe was dug up and no source of leakage could be found. They then took a solution of lithium chloride and poured it into the hospital drain. The chemist of the Board of Health examined the water in the well six hours afterwards spectroscopically, and the lithium chloride was noted, showing contamination of the water supply. Dr. Janeway also told of an institution of learning that had an outbreak of typhoid fever, and it was interesting to note that in the first six cases the persons had their meals together, although they did not live together. It was found that there was a well within forty feet of a cesspool where the excreta were thrown; there was there a girl ill with typhoid fever. There occurred in that institution some thirty cases. A new water supply stopped the outbreak. A great thing that concerned us in the study of the source of typhoid fever was the water. The water in this city for the past six or eight months had been remarkably clear; but there had been times when there seemed to be danger even in bathing in it, it was so dirty. If New York City had a filtration plant, if it did not ruin the city, it would be a good thing. But New York City's financial situation was something awful, it being in debt seven hundred millions of dollars, almost equal to the national debt. Therefore, they must plan the work in a more economical way, and they should think about filtration in the future. The burden of supplying water should be on the shoulders of those people using the water.

Dr. A. Seibert believed that the chief carrier of typhoid infection was the water drank, the same in this as in other countries. Some years ago he made a comparison of the typhoid fever mortality of New York City for ten years, from 1890 to 1900, with that of the Prussian army, and the curve resulting from the study of the one could not be told from the other. The sameness between the two curves showed something in common, and this he believed to be the temperature. A filtration plant should be established in this city. Seventy per cent. of the cases of typhoid fever in cities was due to an infected water supply. So soon as the filtration plant was established, it had been found in other cities, the mortality dropped from one in eight thousand to one in twenty thousand. This was the drop in Hamburg, Breslau, and other cities. Dr. Seibert said that years ago he had listened to a paper by Dr. Bensel regarding the typhoid infected oyster, and he had not eaten one since.

Dr. Jonathan M. Wainwright of Scranton, Pennsylvania, after referring to the typhoid epidemic of Scranton, said that he did not believe that the typhoid in New York City was due to its water supply, and the institution of a filtration plant would not cut down the number of cases. In the Scranton epidemic it was learned that to a large extent typhoid fever was a directly communicable disease. In their epidemic the directly communicable cases ran from 20 to 40 per cent. He believed the time would come when typhoid fever would be looked upon as a communicable disease, as measles and scarlet fever were looked upon to-day, and the health boards should so consider it.

Dr. William H. Park said that Dr. Bensel had shown only the bad points regarding the Croton Water shed, and had neglected to tell them of the good points. At present more time was allowed for sedimentation than formerly. Dr. Park referred to the epidemic of one year ago; about March 1, the number of cases rapidly jumped up in two weeks, and this increase was confined entirely to Manhattan, and there seemed to be nothing to explain it. The Croton dam was drained because it was found to be covered with grass and shrubs, making the water offensive. At that time the water ran rapidly through Croton lake to New York City. It proved to him two things. First, that the number of cases of typhoid was in a measure dependent upon the rapidity of the water flow to this city; the faster the flow, the more cases. Second, it made him believe that Croton water did give some typhoid. With regard to Dr. Seibert's statement with respect to the number of cases increasing with the warm months of the year, this he believes to be due to the growth of the bacilli; the typhoid bacilli died out very quickly in the cold months. Typhoid fever should always be studied as Dr. Wainwright had studied the Scranton epidemic. There was no doubt that there would occur a decrease in the number of cases of typhoid fever when filteration plants were installed. Cities like Albany, where such plants had been introduced, were filtering bad water, but filtered bad water was better of course than such water unfiltered. Oysters in a bad condition made a good soil for the growth of typhoid bacilli. Other things than water should be consid-

ered in the spread of typhoid fever. Fly growth and typhoid growth occurred together, and he had no doubt that some cases of typhoid were caused by flies. Dr. Park then referred to the cook who, although apparently well, was dangerous to the community in which she lived because her feces contained at all times the typhoid bacilli. Some people were persistent typhoid carriers. Three of four per cent. of those who had had typhoid became typhoid carriers for life. As a result of this there were to-day in New York more typhoid carriers than there were cases of typhoid fever.

Dr. JOHN S. THATCHER said that it had been shown in other cities that the municipal government could do much in the way of improving its water supply. Years ago he wrote a paper calling attention to the fact that typhoid fever of cities came from the country in the main. Cities had to be protected by working on the country cases, because it had been demonstrated that typhoid was more prevalent in the rural than in the city districts. Cities got it through the supply of milk, of fruits, vegetables, people coming to the cities from the country, etc. Therefore, it seemed to him that they should work to improve the water supply, filtering the water, licensing the milk and oyster dealers, and this must be supplemented by trying to regulate the general hygiene of the people throughout the rural districts. The fecal hygiene of the country must be improved and we should attempt to educate the legislators as well.

Mr. GEORGE S. SOPER said he had been asked to be present and throw some light upon the reason why typhoid fever was more prevalent in some boroughs of New York than in others, and why there were fifty per cent. more cases in Brooklyn than in the Bronx. The borough of Queens was the most unsanitary borough of the city. There was one creek on Staten Island within three miles of the place where seven million gallons of sewage were emptied. Then again there were from three to six hundred bushels of oysters in these waters. These oysters lose in weight and substance by the process, becoming bloated rather than fattened. He regretted that the Board of Health when it passed a ordinance concerning the licensing of oyster dealers, had not mentioned shell fish dealers as well. Clams were as bad as oysters as disease carriers. A very large quantity of clams came from polluted waters in a near-by State. In that State no objection was made to sending clams to New York. Six hundred thousand oysters were produced annually in the vicinity of New York, and a large number of these were contaminated. Filtration and improving the water supply of cities had reduced the prevalence of typhoid fever only about fifty-three per cent. on an average. In ten cities the typhoid rate averaged 28.5, a very high typhoid rate. The rate for New York City was 8.1. For the whole country the rate was excessive and this he considers a public shame. For this country the rate was about four times what was found to obtain in Europe. How should typhoid be prevented? No one, he said, had mentioned the most simple measures, but forty years ago Samuel Budd gave a method of eliminating typhoid, and it was the only method by which the disease could be suppressed; that was, destroy the infectious nature of the discharges so soon as produced.

Dr. L. R. WILLIAMS thought it would be wise to consider the filtration plant for New York City at some future time and, in the meantime, to mull over the situation and report to the Academy the pro and con in the autumn. He asked if it would not be feasible to appoint a committee to consider the filtration plant question for New York City, that committee to report to the Academy in the autumn.

The PRESIDENT thought this would be feasible and asked for a motion to that effect. The motion was made, and Dr. Wyeth said he would name the Committee soon, and that Dr. Williams would be appointed Chairman.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

MICHIGAN STATE BOARD OF REGISTRATION IN MEDICINE.

Examinations at Detroit, May 25, 26, 27, 1908.

ANATOMY.

1. Give origin, course, and branches of the internal maxillary artery.
2. Describe the thorax (of the skeleton) as a whole.
3. Describe the thyroid gland as to (*a*) size, (*b*) situation, (*c*) structure, (*d*) gross relation, (*e*) blood and nerve supply.
4. Describe the duodenum as to (*a*) size, (*b*) situation, (*c*) structure, (*d*) relations, (*e*) blood supply.
5. Trace the second cranial nerve from its origin to its distribution. (*b*) Describe briefly the structure of the eyeball.
6. Describe the pelvis (as a whole). What variations of form depend on sex, and what on age.
7. Describe the middle fossa of the base of the skull.
8. Describe the spleen under the following heads: (*a*) size, (*b*) situation, (*c*) form, (*d*) relations, (*e*) support, (*f*) blood supply, (*g*) nerve supply.
9. Describe the thoracic part of the sympathetic cord.
10. Describe the axillary artery, giving its relations, naming and indicating briefly the distribution of its branches.

HISTOLOGY AND EMBRYOLOGY.

1. Describe the structure of a sweat gland.
2. Describe the formation of the blood.
3. Give in detail the method of preparing hemin crystals.
4. Name the different kinds of connective tissue.
5. Describe medullated and nonmedullated nerve fibers.

PHYSIOLOGY.

1. Metabolism: (*a*) Define and give classification. (*b*) Discuss the manifestation of cell life.
2. (*a*) What are the functions of the bile? (*b*) What is the average quantity secreted daily, and what is the function of the liver other than the secretion of bile.
3. (*a*) Give location of articulate speech, and (*b*) mention the various forms of asphasia.
4. What is meant by the "refracting apparatus" of the eye, and what are the most common errors relating thereto?
5. State the three divisions of the organ of hearing and give function of Eustachian tube.
6. What changes take place in the composition of the blood as it passes through the kidneys?
7. What is meant by the term "inhibition"? Describe its mechanism.
8. Mention and give function of some one large system of veins beginning and ending in capillaries.
9. Blood: (*a*) Trace its course through the heart and lungs, beginning at the right auricle. (*b*) Describe the changes that take place.
10. What are reflex movements? Give classification and laws governing same.

CHEMISTRY AND TOXICOLOGY.

1. What is a chemical formula? Give chemical formulæ for (*a*) nitric acid, (*b*) sulphuric acid, (*c*) phosphoric acid. Give tests for each.
2. What is ozone; its properties; how recognized; its influence on epidemic diseases? If air, which is rich with ozone, is inhaled, what is the effect on the respiratory organs.
3. What is dextrine? What is starch; how obtained, and by what test can it be recognized?
4. What are ptomains? Give symptoms and treatment of ptomain poisoning.
5. What chemical tests are used for detecting the presence of organic impurities in water?
6. What are the properties and uses of carbolic acid? How is it made? How would you treat a case of carbolic acid poisoning?
7. What are the properties of arsenic? Of what use is the antiseptic quality of arsenic? What is the antidote for arsenic? How prepared?
8. What are the properties of hydrocyanic acid? Give symptoms and treatment of poisoning by same.
9. How is tartar emetic made? Give formula.
10. Name general properties of alkaloids. What are the principal liquid alkaloids?

BACTERIOLOGY.

1. How would you determine, by bacteriological method, if a specimen of drinking water was pure?

2. Describe the *Bacillus anthracis*.
3. What is a parasite? What is a saphrophyte?
4. Define a toxin, and an antitoxin. Explain the theory of disease, and treatment by antitoxins.
5. What are mordants?

PATHOLOGY.

1. Explain metabolism in diabetes.
2. Name the causes of hemorrhage.
3. How are infarcts formed?
4. What is the rôle of the exudate in inflammation?
5. What is pathologieal regeneration?
6. Describe the formation of a dermoid cyst?
7. Give the pathologieal anatomy in acute yellow atrophy of the liver.
8. Name the various forms of cancer of the stomach in order of frequency.
9. How are toxins formed, and how destroyed or eliminated from the system?
10. What changes in the blood-vessels take place in chronie interstitial nephritis?

MEDICAL JURISPRUDENCE.

1. What is the difference between expert and ordinary testimony?
2. How would you determine whether a wound found on a dead body was inflicted before or after death?
3. Define abortion? When is it not a crime?
4. Define insanity from a medicolegal standpoint.
5. In a case of suspected poisoning, give detailed directions for preparing and transferring organs to the ehemist for examination. What organs should be sent?

EYE, EAR, NOSE, AND THROAT.

1. Iritis: give diagnosis and treatment.
2. Ophthalmia neonatorum: give cause, symptoms, treatment, and prophylaxis.
3. Acute suppurative otitis media: give diagnosis and treatment.
4. Epistaxis: give causes, and describe in detail its treatment.
5. Edema of the glottis: give etiology, symptoms, and treatment.

OBSTETRICS.

1. Describe the eorpus luteum of pregnancy.
2. Describe the relation between ovulation and menstruation.
3. Diagnosis of pregnancy.
4. Extrauterine pregnancy: symptoms, diagnosis, treatment.
5. How would you diagnose a shoulder presentation, and what would be your treatment?

GYNECOLOGY.

1. What is ectopic gestation? Give methods of diagnosis and treatment.
2. Give causes of displacements of uterus, symptoms, and treatment.
3. Describe gonorrhea and its sequelæ in the female.
4. Curette: Give indications for using as a means of diagnosis; method of using; dangers of using.
5. Uterine hemorrhage: causes and treatment of each.

SURGERY.

1. What is an abscess? Give pathology.
2. Define appendicitis, and give method of exact diagnosis.
3. Give the best treatment for appendicitis in usual eases and in fulminating eases.
4. What is spina bifida? Give cause, pathology, and treatment.
5. Describe the best method for the restoration of the pelvic floor. Give technique.
6. In compound, comminuted fracture of the tibia, describe treatment fully.
7. In a gunshot wound through the head of the humerus, what would be your management? Give technique.
8. How would you treat a septic infection of the knee joint? Describe fully.
9. Give diagnosis of chanere, chancroid, and herpetie ulcer.
10. Describe snakebite, its symptoms, pathology, and treatment.

MATERIA MEDICA AND THERAPEUTICS.

1. Mention some of the temperature depressants; their manner of action and their doses.
2. What is the therapy of ergot? Mention some of its preparations and their doses.
3. Give the physiological action of strychnine and its toxicology.
4. Mention the methods by which medicines may be administered.
5. What is the general rule for calculating doses for children?

PRACTICE OF MEDICINE.

(Including Neurology and Pediatrics.)

1. Describe intracranial pressures: causes, symptoms, and treatment.
2. Differentiate between hysterical paralysis and paralysis from a spinal lesion.
3. Give causes, symptoms, physical diagnosis, and treatment of acute croupous pneumonia.
4. Deseribe causes, tests, symptoms, and treatment of typhoid fever.
5. Give causes of myocardial insufficiencies.
6. Diagnosis and treatment of pleuritic effusion.
7. Describe acute catarrhal jaundice and treatment.
8. What is vertigo? Give cause and treatment.
9. Differentiate between follicular tonsillitis and diphtheria.
10. Give cause, symptoms, and treatment of enterocolitis in young children.

HYGIENE.

1. Define hygiene.
2. Tell how you would manage a case of typhoid fever to prevent spread of infection.
3. What lower animals are carriers of diphtheritic poison? How manage cases of diphtheria to prevent spread of contagion?
4. How stamp out typhoid fever?
5. How prevent spread of scarlet fever? Of measles?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

MICHIGAN STATE BOARD OF REGISTRATION IN MEDICINE.

Examinations at Detroit, May 25, 26 and 27, 1908.

PHYSIOLOGY.

1. (*a*) *Metabolism* is the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) Assimilative, or constructive (*anabolism*); and (2) destructive (catabolism).

(*b*) The manifestations of cell life are: (1) Irritability, or power of responding to a stimulus; (2) power of movement; (3) power of assimilation; (4) power of growth; (5) power of excretion, and (6) power of reproduction.

2. (*a*) *The functions of the bile* are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has very feeble antiseptic action.

(*b*) The average quantity of bile secreted in twenty-four hours varies from about 500 c.c. to 900 c.c.

The functions of the liver other than the secretion of bile are: (1) The formation of glycogen, (2) the formation of urea and uric acid, (3) the manufacture of heat, and (4) the conversion of poisonous and harmful into inert material.

3. (*a*) The center for articulate speech is thought to be located in the third or inferior frontal convolution of the left cerebral hemisphere; this is often called Broca's convolution.

(*b*) The various forms of aphasia, are: (1) Motor; (2) sensory, which may be (*a*) visual, (*b*) auditory; (3) conduction; and (4) mixed.

4. The *refracting apparatus* of the eye consists of: (1) The *refracting surfaces*, viz., the cornea, and the anterior and posterior surfaces of the lens; (2) the *refracting media*, viz., the aqueous humor, the crystalline lens, and the vitreous body. The most common errors relating to refraction, are: hyperopia, myopia, and astigmatism.

5. The three divisions of the organ of hearing are: (1) the external ear; (2) the middle ear, or tympanum; (3) the internal ear, or labyrinth.

The *function of the Eustachian tube*, is to keep the atmospheric pressure within the tympanic cavity the same as that on the outside.

6. As the blood passes through the kidney it loses water, salts, urea, carbon dioxide, and extractives.

7. *Inhibition* is the voluntary restraining of a reflex act, or of the processes which occur in one part of the nervous system by the activity of some other part. "The central nervous system is functionally united into a whole, and the activity of each part affects the activity of every

other part, *e.g.*, during the act of swallowing, the pulse beats more quickly because the cardioinhibitory reflexes are diminished; sneezing, respiration, micturition, etc., are checked by strong sensory stimulation. If, while the cortex of the Rolandic area of the brain is being stimulated by a current which would ordinarily produce a movement of certain muscles, a strong stimulus be applied to a sensory nerve, the cortical stimulation is rendered ineffective; actions which are ordinarily reflex become voluntary when attention is directed to them. Such instances of inhibition can be explained by supposing (1) that when impulses are passing through a reflex-path, neighboring paths are blocked; (2) that if the route toward a higher center is open, a part of the afferent impulse passes upward to the higher center (the amount of the impulse so directed depending upon the state of attention of the higher center); whereas, when this ascending route is closed, the whole impulse flows across a reflex-path." (Hill, *Physiologists' Note-Book.*)

8. The portal system of veins begins and ends in capillaries. Its function is to carry to the liver blood loaded with material absorbed from the contents of the stomach and intestines.

9. (*b*) In its passage through the lungs, the blood in the pulmonary artery: (1) becomes cooled; (2) becomes a brighter red color; (3) gains oxygen (about 10 or 12 volumes); (4) loses carbon dioxide (about 7 volumes).

10. *Reflex movements* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve.

Reflexes are classified as: (1) Superficial, (2) deep, and (3) visceral.

CHEMISTRY AND TOXICOLOGY.

1. A chemical formula is a collection of symbols representing a molecule and expressing the number and kind of atoms of which it is composed.

The *formula* for (*a*) nitric acid, is HNO_3; (*b*) sulphuric acid, H_2SO_4; (*c*) phosphoric acid, H_3PO_4.

Test for (*a*) nitric acid: Neutralize with potassium hydroxide, evaporate to dryness, then moisten with H_2SO_4, and add a crystal of brucin; a red color appears. (*b*) Sulphuric acid: Add barium chloride, a white precipitate results, which is insoluble in HNO_3 or HCl. (*c*) Phosphoric acid: To dilute HNO_3, add the solution to be tested, and then add a solution of ammonium molybdate; a yellowish precipitate results.

2. Ozone is an allotropic modification of oxygen, in a condition of condensation; thus three molecules are condensed into two molecules of ozone: $3O_2 = 2O_3$.

Properties. It is a dark blue liquid, almost opaque, and is not decomposed at the ordinary temperature. It is very slightly soluble in water, is insoluble in solutions of acids and alkalies; and it is a powerful oxidizing agent.

Test: Paper impregnated with fresh tincture of guaiacum, is colored blue by ozone.

Ozone, being an antiseptic and disinfectant agent, may be supposed to have a restraining influence on epidemic diseases.

If air which is rich with ozone, is inhaled, an acute coryza and catarrh of the respiratory mucous membrane will be produced.

3. *Dextrine,* or British gum, is a substance obtained by subjecting starch to a dry heat. It is like gum arabic in appearance, is soluble in water, and in soluble in alcohol.

Starch is a carbohydrate having the empirical formula $C_6H_{10}O_5$; it exists in plants.

Preparation: "It is prepared from roots or seeds by crushing them and placing them upon a sieve or strainer, through which water is flowing. The water mechanically carries the starch through the sieve, leaving the fibrous and cellular substances behind. The water is then allowed to stand, and the starch deposits as a white sediment, from which the water is poured off, and which is finally dried." (Luff and Page's *Chemistry.*)

Test: A solution of free iodine gives, with starch, a blue color; this color disappears on warming, and reappears on cooling.

4. *Ptomains* are basic, nitrogenous compounds, produced from protein material by the bacteria which cause putrefaction.

Ptomain poisoning. Symptoms: Chilliness, headache, vertigo, muscular twitchings, hallucinations, imperfect vision, weak and rapid pulse, nausea, vomiting, diarrhea, cyanosis, early dyspnea, often subnormal temperature, and occasionally cutaneous eruptions. The prognosis is guardedly favorable.

Treatment consists in the use of emetics and cathartics, or lavage and rectal irrigation. Morphine may be indicated for the relief of pain, and collapse is to be combated by atropine, strychnine, nitroglycerin, external heat, whiskey, etc. After thorough purging, salol, naphthol, or bismuth may be given.

6. Carbolic acid is a colorless crystalline substance when pure, but it soon assumes a pink color; it has a peculiar odor, and a burning taste. It is soluble in water, alcohol, and ether. It is an antiseptic, a poison, and a corrosive. It is also used in the manufacture of its derivatives which are used in medicine, and as dyes. It is made by heating phenyl iodide and potassium hydroxide at a high temperature: $C_6H_5I + KHO = KI + C_6H_5OH$.

The treatment of carbolic acid poisoning consists in administering white of egg, sodium sulphate, or saccharated lime, followed by lavage. Alcohol is said to be antidotal.

7. *The properties of arsenic*: Arsenic is an element, with atomic weight of 75, molecular weight 300, valence three or five; the molecule contains four atoms. It occurs chiefly in combination in orpiment, realgar, mispickel, or iron pyrites. It is a brittle gray solid with metallic luster, or an amorphous powder; the vapor has an odor of garlic; it is insoluble in water; it unites with nascent hydrogen; it burns in oxygen. It is a good conductor of electricity. It is tarnished by moisture; in dry air it is not altered; heated in air it becomes arsenic trioxide. It combines with most metals, also with chlorine, bromine, iodine, sulphur, and with nascent hydrogen.

The antidote for arsenic is a freshly prepared solution of ferric hydroxide; this may be prepared by keeping the two following solutions in separate bottles, and when needed it is only necessary to mix them and administer: (1) Liq. ferri tersulphatis, ℥ij; aquæ, ℥vj. (2) Magnesiæ, ʒiij; aquæ, ℥viij.

8. *The properties of hydrocyanic acid*: It is a colorless liquid, with a penetrating and characteristic odor; it is rapidly decomposed on exposure to light. It is an extremely powerful and rapidly acting poison.

HYDROCYANIC ACID POISONING. *Symptoms*: "Its action is always rapid. Relatively small doses cause an immediate sense of constriction of the throat, followed in one or two minutes by sense of pressure in the head, vertigo, confusion of intellect, and loss of muscular power. The pulse is quick, the respiration slow and stertorous. Tetanic convulsions and involuntary discharges of urine and feces occur, followed by paralysis. Death follows, in from two hours to two days, from asphyxia. When large doses are taken no subjective symptoms are observed. The patient loses consciousness in less than one minute. There is a short convulsive seizure, usually accompanied by evacuations of feces, after which the patient lies perfectly still, with no sign of life, save an almost imperceptible pulse and infrequent spasmodic respiratory efforts, in which inspiration is short and expiration protracted. Death follows in from five to twenty minutes.

Treatment: "There is no time for administration of antidotes. The patient should be stripped, and cold water dashed upon the head and spine, which are them rubbed dry with warm towels, and the cold douche repeated, after which artificial respiration should be practised. Inhalations of chlorine or ammonia, largely diluted with air, are recommended." (Witthaus' *Essentials of Chemistry.*)

9. Tartar emetic is made by boiling antimony trioxide and acid potassium tartrate, in water, filtering, and allowing to crystallize. $Sb_2O_3 + 2KHC_4H_4O_6 = H_2O + 2KSbOC_4H_4O_6$.

10. *General properties of alkaloids*: Alkaloids are of two kinds, volatile and fixed. The volatile alkaloids are liquid, readily volatile without decomposition, and consist of C, H, and N. The fixed alkaloids are for the most part solid and crystalline, not, or only partially volatile without decomposition, and consist of C, H, N, and O.

Most of the alkaloids are alkaline in reaction, of a bitter taste, and of white color.

Most of the alkaloids are nearly insoluble in water, but are soluble in alcohol, chloroform, ether, and benzine; their salts are generally soluble in water and alcohol, but insoluble in the other solvents just named. They combine with acids to form salts in the same way that ammonia does.

The principal liquid alkaloids are: Sparteine, nicotine, and coniine.

BACTERIOLOGY.

2. The *Bacillus anthracis* is a large, rod-shaped microorganism, with slightly thickened ends; it is from 5 to 20 mikrons in length, and a little more than one mikron in breadth; it has a tendency to form long threads; it is nonmotile and nonflagellated; it is aërobic, and stains by all the alkaline aniline dyes and by Gram's method.

3. A *Parasite* is an organism which lives upon or within another (living) organism.

A *Saprophyte* is an organism which lives upon dead organic matter.

4. *Toxins* are the products of pathogenic bacteria or of ptomaines or leucomaines, and are actively poisonous.

An *antitoxin* is a substance formed in the body, of a protective character, and capable of rendering inert the poisonous products of bacteria.

5. A *mordant* is a substance used to fix the dyes used in staining tissues and bacteria.

PATHOLOGY.

1. *Metabolism in diabetes*: "The essential fact is the inability of the body to consume carbohydrates for the production of energy. As long as excess of proteid and fatty food is taken and consumed, no disturbance of the general metabolism results; but when digestion fails or the diet is poorly regulated, destruction of the proteids of the body with increased excretion of urea occurs. Emaciation may be prevented for a time by increased consumption of proteid food, but eventually occurs. In the destruction of the proteids of the food and tissues, acids are formed in excess (phosphoric from the phosphorus, sulphuric from the sulphur, beta-oxybutyric and diacetic from the non-nitrogenous part of the albumins), and the condition termed acid-intoxication results. A consequence, and to some extent a measure, of this is the increased excretion of ammonium salts in the urine. The uric acid of the urine is but little increased in diabetes." (Stengel's *Text-Book of Pathology.*)

2. The *causes of hemorrhage*, are: Injury to the vessel wall; disease of the vessel wall; invasion by tumors; removal of support of the vessel; increased blood pressure; certain diseases and conditions, like hemophilia, scurvy, etc.

3. Infarcts are formed by the plugging of an end artery by an embolus.

5. *Pathological regeneration* is the formation of new cells and tissues to replace those that have been destroyed by disease or traumatism. It occurs generally on a large scale, and often the regenerated parts are not perfectly identical with those which they replace.

8. According to Osler, the most common forms of cancer of the stomach, are the cylindrical-celled adenocarcinoma and the encephaloid or medullary carcinoma; next in frequency is the scirrhous, and then colloid cancer. Sarcomata are very rare.

10. In chronic interstitial nephritis, the blood-vessels are sclerosed and thickened; the most pronounced changes are in the intima; in the outer coats the connective tissue is increased. Arteriosclerosis is generally present.

MEDICAL JURISPRUDENCE.

1. In *expert* testimony, the witness may give his *opinion* on facts or supposed facts as noted by himself or asserted by others. *Theoretically*, this can be done only by those perfectly familiar with the subject in question; but *practically* any (or almost any) physician with a license to practise is accepted as an expert witness.

In *ordinary* testimony, the witness testifies to *facts* which he has seen, or heard, or with which he has become acquainted by personal observation.

2. A wound inflicted during life is generally characterized by hemorrhage, coagulation of the blood, eversion of the edges, and retraction of its sides. It may also be inferred that the wound was inflicted during life if any of the following are noticed: The presence of inflammation, swelling, pus, or gangrene on the edges of the wound, or if there is any sign of beginning cicatrization.

3. Abortion is the premature expulsion of the product of conception (at any period of gestation), whether ovum, embryo, or fetus. It is not criminal when it is due to natural causes, or when done by a physician, after proper consultation, for sufficient cause. The chief conditions that justify the induction of abortion are: (1) Certain pelvic deformities; (2) placenta prævia; (3) pernicious anemia; (4) toxemia of pregnancy; (5) habitual death of the fetus toward the end of pregnancy; (6) hydatidiform mole; (7) habitually large fetal head.

4. According to Taylor, the term insanity is applied to "those states of disordered mind in which a person loses the power of regulating his actions and conduct according to the ordinary rules of society. In all cases of real insanity the intellect is more or less affected."

5. In case of suspected homicidal poisoning, the following parts of the cadaver should be preserved: "The alimentary canal from the cardia to the middle of the rectum, *unopened*, and the contents enclosed by ligatures at the esophagus, duodenum, and lower end of gut; the liver, including the gall-bladder; one kidney; the spleen; a piece of muscular tissue from the leg; the brain, and any urine which may remain in the bladder. They are to be placed in *clean* and *new* glass jars, closed with glass or cork covers or stoppers. Jars with metallic caps should never be used. Tapes or cords should be tied about the jar and cap, to which they should be attached by sealing wax bearing impressions of a seal, in such a manner that access can be had to the interior only after breaking the seals or cutting the tapes or cords. Great care must be exercised that no sealing-wax gets into the jars. Each portion should be placed in a jar by itself." (Witthaus' *Essentials of Chemistry.*)

EYE, EAR, NOSE, AND THROAT.

2. *Ophthalmia neonatorum* is an infectious, purulent inflammation of the conjunctiva in the new-born.

It is *due to* gonococcus or some other pyogenic germ; and is produced by contact of the eye with the vaginal secretion of the mother during labor, or infected fingers, or instruments, etc.

Symptoms: Swelling and redness of the eyes, the presence of a discharge which soon becomes purulent, the conjunctiva of the lids becomes thickened.

Treatment: Wash the eye carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

Prophylaxis: Whenever there is a possibility of infection, or in every case, wash the eyelids of the new-born child with clean warm water, and drop on the cornea of each eye one drop of a 1 or 2 per cent. solution of nitrate of silver, immediately after birth.

OBSTETRICS.

2. The relation existing between ovulation and menstruation is not known. The two processes are usually coexistent, but they may be independent of each other. The following theories have been held: (1) Menstruation is dependent upon ovulation; (2) ovulation is dependent upon menstruation; (3) they are independent of each other; (4) they both depend upon some other (at present unknown) cause.

3. *Positive signs of pregnancy*: (1) Hearing the fetal heart sound; (2) active movements of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle.

Doubtful signs of pregnancy: (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness.

Subjective signs of pregnancy, in the order of their appearance, are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movements.

Objective signs of pregnancy, in the order of their appearance, are: Softening of the cervix, changes in the mammary glands, discoloration of the vulva and vagina, pulsation in the vaginal vault, Hegar's sign, active fetal movements, ballottement, palpation of the fetus, intermittent uterine contractions, hearing the fetal heartbeat, rate of growth of the uterine tumor.

4. See below—GYNECOLOGY, Question 1.

GYNECOLOGY.

1. Ectopic gestation is a pregnancy in which the ovum is developed outside of the uterine cavity.

Diagnosis.—"When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri it patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs*; Nos. 3 and 4 are *probable signs*; Nos. 5 and 6 are *positive signs*." (*American Text-Book of Obstetrics.*)

Treatment consists in the removal of the product of conception by a laparotomy, as soon as the diagnosis is made.

5. The following (from Gould and Pyle's *Cyclopedia of Medicine and Surgery*) is a useful classification of uterine hemorrhages, and also gives the causes of the same:

I. *Hemorrhages Complicating Pregnancy, Labor, or the Puerperium*:

A. Hemorrhages of Pregnancy: caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) apoplexy of the decidua or placenta.

B. Hemorrhages of Labor: caused by (1) placenta prævia; (2) premature separation of a normally situated placenta; (3) relaxation of the uterus; (4) laceration of the cervix; (5) rupture or inversion of the uterus.

C. Hemorrhages of the Puerperium: caused by (1) retained secundines; (2) displaced uterus; (3) displaced thrombi; (4) fibroid tumors; (5) hypertrophied decidua; (6) carcinoma.

II. *Hemorrhages Occurring in the Non-Pregnant Woman:*

A. In Virgins Before the Age of Thirty: caused by (1) uterine congestion, the result of cold or exposure; (2) endometritis; (3) polypi and fibroid tumors.

B. In Married Women Before the Age of Thirty: caused by (1) subinvolution; (2) laceration of the cervix; (3) endometritis; (4) retrodisplacements of the uterus; (5) polypi and fibroid tumors.

C. In Women after the Age of Thirty: caused by (1) carcinoma of the cervix; (2) carcinoma of the body of the uterus; (3) sarcoma of the uterus.

MATERIA MEDICA AND THERAPEUTICS.

1. The following table (from Potter's *Materia Medica*) gives the chief temperature depressants, with their manner of action: Temperature depression may be done by five different actions working upon two principal lines, viz., by—

(*a*) *Lessening heat production, by*
- (1) diminishing tissue change.
- (2) reducing the circulation.

(*b*) *Promoting heat loss by*
- (3) dilating cutaneous vessels, thus increasing heat radiation.
- (4) promoting perspiration—its evaporation lowering the temperature.
- (5) abstracting heat from the body.

The following list of antipyretics includes a few for each of the above-named actions, to which the numbers refer in each case, viz.:

Quinin, 1.	Aconite, 2.	Antipyrin, 1, 4.
Phenol, 1.	Alcohol, 1, 3.	Antimony, 2, 4.
Salicin, 1.	Nitrous ether, 3, 4.	Cold bath, 5.
Digitalis, 2.	Acetanilid, 1, 4.	Cold drinks, 5.
	Phenacetin, 1, 4.	Wet-pack, 5.

3. Strychnine. *Physiological action*: Strychnine is a bitter tonic, stimulates appetite, secretion, and digestion, increases peristalsis, stimulates the vasomotor centers, and so raises arterial tension, and stimulates both accelerator and inhibitory nerves of the heart. All the functions of the spinal cord are exalted by strychnine, reflex, motor, vasomotor, and sensory. Large doses cause dilated pupils, irregular and jerky respiration, increased reflexes.

The *symptoms of poisoning by strychnine* are "a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours."

Treatment: "The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible." (Witthaus' *Essentials of Chemistry.*)

4. *Medicine can be administered*: (1) By the mouth; (2) by the rectum; (3) by inhalation; (4) by inunction; (5) hypodermically; (6) by intravenous injection; (7) by fumigation; (8) by cataphoresis.

5. Let x = the age of a patient; then $\frac{x}{x+12}$ = the fraction of the adult dose which the patient should receive. Thus, a patient of four years old should receive $\frac{4}{4+12} = \frac{4}{16} = \frac{1}{4}$ of an adult dose.

HYGIENE.

1. Hygiene is the science and art of all that tends to the maintenance and improvement of health, the prevention or shortening of the duration of diseases, and the prolongation of life.

2. Typhoid fever is preventable. All water for drinking or for washing dishes, etc., and milk should be boiled; no ice should be put *in* water or other drink or food; flies should be kept out of the house; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed, and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over.

3. Cats, cows, pigeons, and turkeys are said to be carriers of diphtheritic poison. To prevent the spread of contagion in cases of diphtheria, the patient should be isolated in the mildest attack, physician and nurse should use antiseptics and also a disinfectant gargle after coming in contact with the patient, sputum must be burnt, those in attendance must avoid the spray of the expectoration, the room and fittings must be thoroughly disinfected after the termination of the disease. Prophylactic doses of antitoxin may be administered to those exposed to the disease.

4. See No. 2, above.

BULLETIN OF APPROACHING EXAMINATIONS.†

STATE.	NAME AND ADDRESS OF SECRETARY.	PLACE AND DATE OF NEXT EXAMINATION.	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 5
Arizona*	Ancil Martin, Phoenix	Phoenix	Oct. 5
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Oct. 13
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	San Francisco	August 4
Colorado	S. D. Van Meter, 1723 Tremont Street, Denver	Denver	Oct. 6
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov. 10
Delaware	J. H. Wilson, Dover	Dover	Dec. 8
Dist. of Col'bia	Geo. C. Ober, Washington	Washington	Oct. 13
Florida*	J. D. Fernandez, Jacksonville	Jacksonville	Nov. 11
Georgia	E. R. Anthony, Griffin	Atlanta	Oct. 6
Idaho	W. F. Howard, Pocatello	Boise	Oct. 6
Illinois	J. A. Egan, Springfield	Chicago	July 22
Indiana	W. T. Gott, 120 State House, Indianapolis	Indianapolis	Oct. 27
Iowa	Louis A. Thomas, Des Moines	Des Moines	Sept. —
Kansas	D. P. Cook, Clay Center	Kansas City	Oct. 13
Kentucky*	J. N. McCormack, Bowling Green	Louisville	Oct. 27
Louisiana	F. A. LaRue, 211 Camp Street, New Orleans	New Orleans	Oct. 1
Maine	Wm. J. Maybury, Saco	Augusta	
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 8
Massachusetts*	E. B. Harvey, State House, Boston	Boston	Sept. 8
Michigan	B. D. Harison, 205 Whitney Building, Detroit	ansing	Oct. 13
Minnesota	W. S. Fullerton, St. Paul	St. Paul	Oct. 6
Mississippi	S. H. McLean, Jackson	Jackson	Oct. 13
Missouri	J. A. B. Adcock, Warrensburg	Kansas City	Nov. 23
Montana*	Wm. C. Riddell, Helena	Helena	Oct. 6
Nebraska	E. J. C. Sward, Oakland	Lincoln	Aug. 5
Nevada	S. L. Lee, Carson City	Carson City	Nov. 2
N. Hampshire*	Henry C. Morrison, State Library Concord	Concord	
New Jersey	J. W. Bennett, Long Branch	Trenton	Oct. 20
New Mexico	J. A. Massie, Santa Fe	Santa Fe	Oct. 12
New York	C.F.Wheelock, Univ. of State of New York, Albany	New York / Albany / Syracuse / Buffalo	Sept. 22
N. Carolina*	G. T. Sikes, Grissom	Winston,Salem	
N. Dakota	H. M. Wheeler, Grand Forks	Grand Forks	Oct. 6
Ohio	Geo. H. Matson, Columbus	Columbus	Dec. 8
Oklahoma*	J. C. Mahr, Shawnee	Shawnee	Sept. —
Oregon	B. E. Miller, Portland	Portland	
Pennsylvania	N. C. Schaeffer, Harrisburg	Philadelphia / Pittsburg	
Rhode Island	G. T. Swarts, Providence	Providence	Oct. 1
S. Carolina	W. M. Lester, Columbia	Columbia	June 8
S. Dakota	H. E. McNutt, Aberdeen	Deadwood	Jan. 13
Tennessee*	T. J. Happel, Trenton	Memphis / Nashville / Knoxville	May,'09
Texas	G. B. Foscue, Waco	Waco	
Utah*	R. W. Fisher, Salt Lake City	Salt Lake City	Oct. 5
Vermont	W. Scott Nay, Underhill	Montpelier	Jan. 12
Virginia	R. S. Martin, Stuart	Lynchburg	Dec. 6
Washington*	C. W. Sharples, Seattle	Seattle	Jan. 5
W. Virginia	H. A. Barbee, Point Pleasant	Wheeling	Nov. 10
Wisconsin	J. V. Stevens, Jefferson	Madison	
Wyoming	S. B. Miller, Laramie	Laramie	Oct. 14

* No Reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State

Therapeutic Hints.

Painful Rheumatic Joints.—In chronic cases the following may be of service:

℞ Acid salicyl.....3i.
Ol. terebinth.....3i.
Adep. lanæ.....
Adep. benzoin.....āā 3i.

M. F. ung.—*The Hospital.*

Chapped Hands.—

℞ Pot. hydrox.....gr. viii.
Glycerini.....3v.
Spt. vini. rect.....3v.
Aquæ.....3ii.

M. S.: Wash the hands with warm water and rub in the lotion freely.—*The Hospital.*

Enuresis.—The following formulæ by Sheffield are recommended in the treatment of enuresis:

℞ Ext. ergot.....3iij.
Ext. rhus toxicodendron.....3j.

M. Sig.: Five to ten drops every four to six hours.

In cases of incontinence due to hyperesthesia of the neck of the bladder, irritating foods should be avoided, sitz baths employed and the following antispasmodic mixture given:

℞ Ext. hyoscyami.....3ss.
Sodii bromidi.....3j.
Aq. anisi.....3j.
Syr. simp.....q. s. ad. 3ij.

M. Sig.: One teaspoonful every four to six hours. Counterirritation by means of mustard plasters should be employed over the lumbosacral region.—*Jour. of the American Medical Association.*

Pruritus.—

℞ Phenolis.....3ss.
Pulv. calamin.....3i.
Zinci oxidi.....3ii.
Glycerini.....3iii.
Aquæ calcis.....3i.
Aquæ rosæ.....3iv.

M. S.: To be applied repeatedly over the surface.

℞ Picis liquidæ.....3iv.
Pot. caustici.....3ii.
Aquæ.....3x.

M. S.: Dilute ten to twenty times with water and apply to the surface, which is afterward covered with an ointment.—*Bulkly.*

Gastroptosis.—

℞ Chloral hydrat.....3i.
Sodii bromidi.....3iiss.
Aq. chloroformi.....3iv.
Spts. anisi.....gtt. vi.

M.
S.: Teaspoonful in water after meals three times a day.—*Lockwood.*

Diphtheria.—If antitoxin cannot be obtained Dempsey recommends the following:

℞ Pot. chlorat.....3ss.
Tinct. ferri. chlor.....3i.
Aquæ dest. ad.....3iii.

M. S.: A teaspoonful in one-fourth glass of water as a gargle, spray or application.—*New Orleans Medical and Surgical Journal.*

Cystitis.—Kreissl uses the following:

℞ Decoct. sem. lini.....10–150.0
Salol.....4.0
Tinct. opii.....gtt. xx.
Syr. simpl.....30.0

M. S.: A tablespoonful every two hours.

℞ Extr. opii.....0.18
Extr. belladon.....0.06
Olei theobrom.....6.0

F. suppos. No. vi.

S.: One suppository two to three times a day.—*Clinical Review.*

Chlorine Gargle.—

℞ Potassii chloratis.....gr. xv.
Acid hydrochlor.....3 ss.
Aq.....q. s. ad. 3 vi.

When well dispensed this should be green in color. The secret lies in using crystals of the salt, strong acid, and a dry bottle. After decomposition is complete the water is added in small quantities at a time.—*The Hospital.*

Ointment for Pruritus Vulvæ.—

℞ Chloral hydrat.....gr. xx.
Gum camphor.....gr. xx.

Rub together in a mortar until they liquefy, then add:

℞ Pulv. acaciæ.....gr. xx.
Simp. cerat.....3 i.

M. Sig.: Apply a little of the mixture with the finger whenever the parts burn or itch.—CLENDENNEN.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 11, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	444	107
Diphtheria	235	33
Measles	431	14
Scarlet Fever	187	16
Smallpox	—	—
Varicella	47	—
Typhoid Fever	72	10
Whooping Cough	18	3
Cerebrospinal Meningitis	6	5
Malarial Fever	—	—
Totals	1440	188

Health Report.—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending July 10, 1908:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
Alabama, Mobile	June 13–20	7	..
California, Los Angeles	June 13–20	1	..
San Diego	To June 13	100 cases, estimated, and mainly in vicinity of the Pala Indian Reservation.	
San Francisco	June 13–20	4	..
Iowa, Davenport	June 1–30	3	..
Sioux City	June 1–30	2	..
Kentucky, Covington	June 20–27	3	..
Louisiana, New Orleans	June 20–27	5	1
Missouri, Conway	Apr. 20–May 24	29	..
Kansas City	June 20–27	1	..
Ohio, Cincinnati	June 19–26	4	..
Dayton	June 20–27	1	..
Troy	To July 3	28	..
Rhode Island, Pawtucket	June 12	1	..
Tennessee, Dickson	June 12	9	..
Texas, San Antonio	Jan. 20–27	1	..
Vermont, Whiting	May 5	1	..
Washington, Spokane	June 13–20	17	..
West Virginia, Moundsville	June 17–July 2	1	..
Wisconsin, La Crosse	June 20–27	3	..

SMALLPOX—INSULAR.

Porto Rico, Mayaguez	June 6–20	4	..

SMALLPOX—FOREIGN.

Canada, Halifax	Jan. 13–20	6	..
China, Amoy (Kulangsu)	Apr. 6–May 16	..	Present
Foochow	May 23–June 6	..	"
Shanghai	May 18–24		3
Cochin-China, Cholon	May 23–30	5	1
Ecuador, Guayaquil	May 23–30	..	4
Egypt, Cairo	May 27–June 3	6	2
Germany, General	May 30–June 6	6	..
Java, Batavia	May 2–30	14	1
Portugal, Lisbon	May 30–June 16	10	..
Russia, Moscow	May 23–June 6	69	27
Riga	June 6–20	5	..
St. Petersburg	May 16–June 6	40	33

A BRIEF ACCOUNT OF THE HISTORY OF MEDICINE IN THE PROVINCE OF QUEBEC, FROM 1535 TO 1838.*

By HERBERT S. BIRKETT, M.D.,

MONTREAL.

PROFESSOR OF OTOLARYNGOLOGY, MCGILL UNIVERSITY, MONTREAL; OTOLARYNGOLOGIST, ROYAL VICTORIA HOSPITAL, MONTREAL; FELLOW OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION.

Fellows of the American Laryngological Association:

Permit me to express my deep sense of appreciation of the honor you conferred upon me in electing me your President. It has been my endeavor to discharge the responsibilities of this high office to the best of my abilities, and I trust to your satisfaction, and with credit to the Association.

It is with very great pleasure that the Medical Profession of this city and of this Dominion welcome you to the first convention of this Association to be held on Canadian soil. Your loyal support in the preparation for this year's meeting and especially the cooperation of our able Secretary, have enabled us to present an excellent program of papers for your consideration. I can only add that we shall endeavor to make your brief stay in Montreal as pleasant as I trust it will be profitable.

It is fitting that I should refer on such an occasion to the loss which this Association has sustained by the death on the 9th of December last, of one of our most eminent corresponding members, Professor Moritz Schmidt.† Perhaps I may recall to you the chief points in his brilliant career. He was born in Frankfort-on-Main on the 15th of March, 1838. He studied in Göttingen, Vienna, Berlin, Utrecht, England, and France, and graduated in 1860. After the practice of general medicine for twenty-six years, he began in 1886 to devote his time exclusively to diseases of the ear, nose, throat, and lungs. He retired from practice in 1903, after receiving signal honors from his colleagues and his Sovereign. He made many valuable contributions to laryngology, most notably the work with which you are no doubt familiar, on diseases of the upper respiratory passages.

At the recent Tuerck-Czermak Jubilee, this Association was unfortunately not represented, but our good wishes were conveyed to the President through a letter from the Secretary.

We have to chronicle a sad event in connection with this Jubilee, in the sudden death from cardiac syncope on Wednesday morning, April 25, of our recently elected Honorary Fellow, Professor Leopold von Schroetter, who had on the previous day delivered, apparently in the best of health, the oration on the opening of the First International Congress of Rhinolaryngology.

Hofrat Professor Dr. Leopold von Schroetter,* Ritter von Kristelli, was born in Graz on the 27th February, 1837. He studied medicine at Vienna, and graduated in 1861, receiving immediately an appointment as Assistant to Skoda, after whose death he acted as substitute in the professorship of clinical medicine. In 1875 he became extraordinary professor of throat and chest affections. In 1881 he was appointed Director of the clinic for laryngology in the Allgemeine Krankenhaus. This position he relinquished in 1890 to accept the professorship of clinical medicine, which position he was about to resign, having reached the age limit of seventy.

His principal writings of laryngological interest are: "Laryngologische, Mittheilungen" (1875), "Beitrag zur Behandlung der Larynxstenosen" (1876), "Vorlesungen ueber Krankheiten des Kehlkopfs," etc. (1867), "Vorlesungen ueber Krankheiten der Trachea" (1901), besides many important papers on clinical medicine. He took great interest in tuberculosis, and was the founder of the celebrated Austrian Sanitorium "Alland." Together with Stoerk and Schnitzler, he was one of the three great laryngological authorities of Vienna. Finally, his taking part in the celebrated November Consultation of 1887 in the case of the then Crown-Prince of Germany, has become historical.

Dr. Newcomb, our worthy Secretary, has but expressed, I am sure, our concordant wish in conveying to the families of our deceased members, the sincere condolences of this Association on the loss of such distinguished men.

The unique significance of this time and place have suggested to me the topic upon which I am to address you. I feel that the honor which you have conferred upon me in electing me your President is in a sense international, and may perhaps justify the choice of a subject which is in a measure national in its scope. It occurred to me that a brief account of the early history of medicine in the province of Quebec might not be inappropriate in a meeting which is held for the first time in the history of the Association in Canada, in this, the oldest Province of the Dominion, and on this, the tercentenary of the founding of Quebec by Samuel de Champlain.

On the 3rd of July, 1908, Canada will celebrate the three-hundredth anniversary of the foundation of Quebec, the real birthday of the Canadian nation. The history of medicine in this Province, however, began seventy-three years before, when Jacques Cartier built his rude fort on the banks of the St. Charles, facing the Indian village of Stadaconé.

It was on the 14th of September, 1835, that Cartier chose this place as a temporary shelter, and leaving his men to construct an abode against the

*Presidential address delivered before the thirteenth annual congress of the American Laryngological Association, held in Montreal, Canada, on May 11, 12, and 13, 1908.

†I desire to express my indebtedness to my friend, Sir Felix Semon, K.C.V.O., for the notes kindly supplied regarding the deceased members.

approaching winter, sailed up the river St. Lawrence as far as the village of Hochelaga, the site of which includes a part of the grounds of McGill University.

Upon his return to Stadaconé, he found the little fort in a state of alarm. Scurvy had broken out in the Indian villages, and according to the account of the leader of the tribe, fifty had already succumbed. Every precaution possible was taken to prevent intercourse with the natives; but nevertheless the disease began to manifest itself among Cartier's crew, "insomuch as some did lose all their strength, and could not stand on their feete, then did their legges swel, their sinnowes shrinke as blacke as any cole. Others also had all their skins spotted with spots of blood of a purple coulour; then did it ascend up to their ankels, knees, thighes, shoulders, armes and necks: their mouth became stincking, their gummes so rotten that all the flesh did fall off, even to the rootes of the teeth, which did also almost all fall out. With such infection did this sickness spread itselfe in our three ships, that about the middle of February, of a hundreth and tenne persons that we were, there were not ten whole, so that one could not helpe the other, a most horrible and pitifull case, considering the place we were in, forsomuch as the people of the countrey would dayly come before our fort and saw but few of us. There were alreadie eight dead, and more than fifty sicke, and as we thought, past all hope of recovery."

The winter wore on; disease and death fell like a pall over the little fort, and Cartier was threatened with a danger more to be feared even than scurvy. Upon the heights of Cape Diamond stood the villages of the Ajoaste, Starnatam and Tailla, branches of the ferocious Iroquois, the first passion of whose souls was war. Hitherto they had been overawed by the presence of the wonderful ships manned by sturdy crews, but gradually, as signs of activity disappeared among the white men, they grew bolder, and at any moment the sound of the war-whoop might be the signal for an invasion of the ships.

Among the crew, there was evidently a man possessing a knowledge of surgery, who determined to hold a postmortem on the body of one Philip Rougemont, 22 years of age; to ascertain the cause of death, and, if possible, save the remnants of the ship's company. Here, in the quaint language of the time, is the result of the first autopsy held in Canada: "He was found to have his heart white, but rotten, and more than a quart of water about it; his liver was indifferent faire, but his lungs blacke and mortified, his blood was altogether shrunke about the heart so that when he was opened, great quantitie of rotten blood issued out from about his heart; his milt towards the backe was somewhat perished, rough as if it had been rubbed against a stone. Moreover, because one of his thighs was very blacke without, it was opened, but within, it was whole and sound: that done, as well as we could he was buried."

The captain was a man of observation. Walking one day on the ice, he perceived a band of the Indians from Stadaconé; amongst them was one Domaguaya, who, less than two weeks before, was in the grip of the disease, "with his knees swolne as bigge as a child of two years old, all his sinews schrunke together, his teeth spoyled, his gummes rotten and stincking. Our captain seeing him whole and sound, was thereat marvellous glad, hoping to understand and know of him how he had healed himselfe, to the end that he might ease and help his men." from Domaguaya he learned that the specific was the bark and sap of a certain tree called in their language "Ameda." This tree is known today as "Tepinette," or the spruce. The method of preparation was as follows:

"To take the bark and leaves of the sayd tree, and boile them together, then to drink of the sayd decoction every other day, and to put the dregs of it upon his legges that is sicke: moreover they told us that the vertue of that tree was to heale any other disease."

The sailors in those days as in these were troubled with another complaint, "French Pockes," but after liberal doses of the bark, they "were cleane healed." From this time forth, the decoction was at a premium and men were ready to kill each other in their eagerness to test its efficiency, "so that a tree as big as any oake in France, was spoiled and lopped bare, and occupied all in five or six daies, and it wrought so wel, that if all the phisicians of Montpelier and Lovaine had bene there with all the drugs of Alexandria, they would not have done so much in one yere, as that tree did in sixe daies, for it did so prevaile, that as many as used of it, by the grace of God, recovered their health."

With the opening of navigation, however, Cartier returned to France, prepared for fresh deeds of adventure. Brave, indeed, were the hearts of those men who lived their lives under the perpetual menace of destruction, facing the perils of the deep to meet the still greater dangers of pestilence on land. Steadfast, heroic, subdued only by the grim reaper, Death, such were the discoverers of old.

Cartier visited our shore again, and spent another winter under scarcely more favorable conditions, notwithstanding that he had found a sovereign remedy for scurvy. With his departure from our shores in 1542, a curtain falls over the history of the country, between Stadaconé and Hochelaga, for a period of sixty years, and we find no reliable account of a settlement on the banks of the Saint Lawrence. Nevertheless, in the year 1578, there were one hundred and fifty vessels engaged in trade with France in the Saint Lawrence, and over two hundred ships belonging to the English, the Spanish, and the Portuguese. We may presume, therefore, that there were temporary settlements, and it is probable that medical supervision in some form was not overlooked.

In the month of April, 1604, Des Monts undertook to colonize New France, and among the men who accompanied him was Louis Hébert, an apothecary, born in Paris. Hébert remained at Port Royal until the month of August, 1607, when the settlement was abandoned. Ten years later, he was invited by Champlain to take up his residence at Quebec, and he was among the first real settlers who cultivated the soil for a livelihood.

His residence was in the Upper Town, near the Basilica. He soon became a prominent figure in the little community, and in 1621 was named "Royal Procurator." The first entry of a marriage in Quebec is that of Hébert's daughter. In 1626 he was granted the fief St. Joseph on the river Saint Charles, with the title of Sieur d'Espinay. He died in January, 1627, as the result of an accident, and was buried in the cemetery of the Récollets. He appears to have been held in high esteem by the Governor, the Récollets, and the citizens.

When Champlain arrived in Canada in 1608, he left his ships at Tadoussac, near the Saguenay, and sailed up the Saint Lawrence in a small craft to found the future city of Quebec. In his company were a number of mechanics, and a surgeon named Bonnerme. The axemen felled the trees on the

narrow belt which skirts the promontory of Cape Diamond, and soon a modest building arose, rudely fashioned into a fort, styled the "Abitation de Québec." While this building was in the course of construction a plot was developing to murder Champlain and deliver Quebec into the hands of a band of Spaniards at Tadoussac. Bonnerme was suspected of complicity in the plot, but his innocence was established and he was released. He died, however, during the winter from the effects of either scurvy or dysentery. It is difficult to determine which disease decimated the colony.

Among the earliest settlers in Quebec was Adrien Duchesne, a surgeon of Dieppe, who probably arrived in 1618. When Champlain surrendered the fort to Sir David Kirke in 1629, Duchesne remained and practised his profession under the English régime. The colony was restored to France in 1632, under the treaty of St. Germain-en-Laye, and a year later Champlain returned as Governor. A few months before the death of the Governor in 1635 Duchesne received a grant of land from the Crown and later transferred it to Abraham Martin, after whom the Plains of Abraham were named. In 1645-6 we find him interested in the young Charles Lemoine, *Seigneur* of Longueuil, and father of the famous Iberville. His practice extended from Quebec to the post at Three Rivers, midway between Quebec and Montreal.

Another surgeon, a contemporary of Champlain, was Robert Giffard, Sieur de Beauport, a native of Mortagne au Perche in France. He was born in 1587 and came to Quebec in 1628 in the capacity of surgeon to the company of "The Hundred Associates." He resided on the Beauport shore and appears to have spent his leisure in hunting and fishing. A year later, however, Quebec fell into the hands of the English, and he returned to France. After the restoration, he obtained a grant of the Seigneury of Beauport in 1634. He was evidently a man of considerable influence and enterprise, for within the space of two years he induced fifty excellent families to settle on the banks of the Saint Lawrence.

The task of colonization in those days was exceedingly difficult. Canada was under the monopoly of the great fur trading companies, whose policy was opposed to any extensive plan of settlement. A sufficient number of residents to facilitate trade was all that was thought desirable. His efforts, therefore, under the circumstances, were remarkable.

In 1647 Giffard obtained a larger grant of land, known as the fief St. Gabriel. A year later, he was appointed a member of the Council, a body empowered to enact local laws and to arbitrate the differences of private individuals. He practised his profession in Quebec and in the surrounding country, and was visiting physician to the Hôtel Dieu, founded in 1639. Giffard was recognized as a man of considerable importance in his time, and when he died in 1648 the community of the Hôtel Dieu felt that they had lost not only an eminent physician, but a true friend.

The colony founded by Champlain at the foot of Cape Diamond had been in existence for half a century, but its institutions were still very primitive. In 1658 Jean Madry, a surgeon of Quebec, while on a visit to France, obtained from the Sieur Barnois, Premier Surgeon in Ordinary to the King, and Provost of the Royal College of St. Come, in the University of Paris, "Letters of Surgeon" for himself, with power to establish in all parts of Canada the authority of surgery in order that the sick might receive more efficient medical care. These letters were registered in the Sovereign Council at Quebec, but they do not appear to have been of much service to the profession. Little appears to have been preserved regarding Madry. He was elected the first Mayor of Quebec, an office which was abolished after a trial of five weeks. The machinery of municipal government was too complicated and expensive for the needs of a community of less than five hundred souls.

There was at this time evidently a need of more physicians to attend the wants of the settlers, for we find that Jean Martinet, Sieur de Fonblanche, who was born in Moustiers, Bourgogne, undertook to teach his brother-in-law, Paul Prudhomme, the art of medicine and surgery by the system of apprenticeship. This is the first recorded instance of a method of teaching, which subsequently became much in vogue. This system led to such an increase in the number of physicians that keen competition and rivalry resulted in the establishment of a form of "combine" or partnership. Those entering into such a partnership "pooled all their possessions, furniture, provisions, roots, and peltry; all the products which they gathered from the ground, their instruments of surgery, their medicines, and lastly, all the revenue which they would obtain from their work and industry." It was further agreed that each of them would devote himself to the profit of the partnership as far as lay in his power, and that he would not run into debt (without the authority of his associates) exceeding the sum of five sous. At the end of four years the profits were equally divided. It was further stipulated that in the case of the death of a member before the expiration of this term, all the goods of the community would belong to the survivors.

An interesting physician of this period was Dr. Gaulthier, who, as a corresponding member of the Royal Academy of Sciences, had made many botanical observations in Canada. It was he who discovered the wintergreen plant, which to-day carries his name, and is known as the "Gaultheria Procumbens." Gaulthier devoted himself also to the study of law under the tutorship of the Sieur Verrier, Procurator-General.

With the considerable increase of population, not only at Quebec, but also at Ville-Marie (Montreal), disease in various forms had become much more prevalent. Smallpox, especially, had spread to such a degree that it was necessary to provide some suitable place to care for and attend the unfortunate sick.

The Duchesse d'Aiguillon, finding such an unfortunate condition of affairs, decided to found a hospital, and sent from Dieppe a certain number of nuns. She received a grant of land in 1637, and established in 1639 the Hôtel Dieu at Quebec. Of the attending staff of this hospital there is one who deserves especial notice, Michel Sarrazin, who came to Canada in the capacity of Surgeon-Major of the French troops. After practising his profession in Quebec for some years he returned to France for the purpose of pursuing his medical studies at the University of Rennes. Three years later he received the title of Physician to the King, and was delegated by the Academy of Science of France to make a special study of animals and plants in Canada. His work in this direction was remarkable. In the Transactions of the Academy of Science for 1704 there appears a paper by Sarrazin on the "Anatomy of the Beaver" which even to-day is regarded as the best work on the subject. His further anatomical researches dealt with the muskrat,

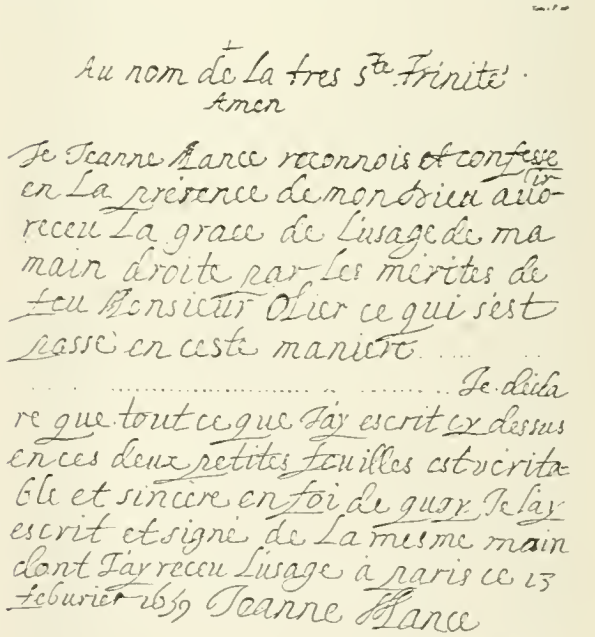
the seal, and groundhog. He also investigated the mineral waters at Cap de la Madeleine. In his botanical researches he discovered the pitcher plant, which is known to-day as the "Sarracenia Purpurea." In recognition of these extensive researches he received a pension of 550 pounds. To Sarrazin's skill as a physician the records of the Hôtel Dieu bear ample testimony.

Expansion and colonization in this new country frequently followed in the wake of missionary activity. "Not a cape was turned," writes Parkman, "but a Jesuit led the way." Few more striking examples of religious enterprise are to be found than the establishment of the little colony at Ville-Marie (Montreal). The founders were Jérôme Royer de la Dauversiere, receiver of taxes at La Fleche in Anjou, and Jean Jacques Olier, a young priest of Paris. To both of these men there came at nearly the same time (1636) the idea of founding a religious colony at Montreal. They formed an association for this purpose and called it the "Society of Montreal." At first the society consisted of six members, but the number was soon increased to forty. Among these was Madame de Bullion, who gave 42,000 livres for the purpose of endowing a hospital in the new settlement. In 1641 Paul du Chomedey, Sieur de Maisonneuve, set out for New France with a company of 100 soldiers under his command. Among those who joined the expedition was Mademoiselle Jeanne Mance, the descendant of an honorable and influential family in France, who became a member of the Society of Montreal. To Mademoiselle Mance was entrusted the control of the funds given by Madame de Bullion, for the establishment of a hospital at Montreal. On the arrival of the expedition in the Saint Lawrence, the summer was found too far advanced to proceed to Montreal, so the winter was spent in Quebec. Many efforts were put forth to dissuade the company from pushing on to Montreal, but in vain. The following spring they sailed up the Saint Lawrence and took possession of the island on the 17th May, 1642. The settlement was named Ville-Marie in honor of the Virgin Mary, to whom it was especially dedicated.

Of a hospital, however, there seemed for a time to be little need. The colony was exceptionally free from sickness, and there were as yet no wounded to be attended, for the Iroquois knew nothing of the little settlement and left the colonists to build in peace. Mlle. Mance even suggested that the endowment for the hospital be given to the Jesuit Missions. To this, however, Madame de Bullion refused to consent. Work on the hospital was continued, and the building was opened on the 8th of October, 1644. There were two rooms for the sick, a room for Mlle. Mance, a kitchen, apartments for the servants, and a chapel 10 feet square, built of stone. During the following year the furniture, medicine, and surgical instruments arrived, and some live stock was brought for the use of the inmates. The usefulness of such an institution was soon conceded, for scarcely had the walls been completed when news of the settlement reached the Iroquois and encounters with the savages began. The wounded were among the first to reap the benefit of the shelter and careful attention which the hospital afforded.

A few years later it was rumored that the "Society of Montreal" had lost interest in the undertaking, and was on the point of dissolution. This prompted Mlle. Mance to return to France and approach Madame de Bullion for further assistance for the hospital. In this she was entirely successful. It now became evident as the work of fortification went on that the hospital was likely to become permanently established. The Iroquois, however, decided to renew their attempts to destroy it. In July, 1651, the hospital was besieged, and had to be abandoned. The defenders took refuge in the fort. The colony was in danger of destruction and it was necessary to have reinforcements. To procure aid, Maisonneuve undertook a journey to France, for which the hospital endowment furnished the money. Upon his return with more than 100 men a new hospital was built and opened in the spring of 1654. The reinforcement of men brought by Maisonneuve put new life into the colony, and enabled them successfully to resist the Iroquois. Thus, a second time, Mlle. Mance, by her judicious use of the endowment funds of the hospital, saved the colony of Montreal.

In 1657 Mlle. Mance, who had been Directress of the hospital since its foundation, fell on the ice, fractured her right arm, and dislocated her wrist. Etienne Bouchard, a surgeon, set the arm, but failed to discover the dislocation of the wrist. Jean Madry also examined her injuries but with no better success. The arm remained entirely useless until Mlle. Mance's temporary return to France occasioned by the financial needs of the hospital. Here the use of her arm, pronounced by the most eminent surgeons in Paris to be beyond recovery, was miraculously restored by touching the casket containing the heart of M. Olier. Mlle. Mance issued the following statement in writing, regarding the miraculous cure:



Au nom de La tres Ste. Trinité.
Amen

Je Jeanne Mance reconnois et confesse en La presence de mon bieu avoir receu La grace de L'usage de ma main droite par Les merites de feu Monsieur Olier ce qui s'est passé en ceste maniere . . . . . Je declare que tout ce que J'ay escrit cy dessus en ces deux petites feuilles est veritable et sincere en foi de quoy Je L'ay escrit et signé de La mesme main dont J'ay receu L'usage à paris ce 13 feburier 1659 Jeanne Mance

"Au Nom de la Tres Sainte Trinite, Amen."

"Je, Jeanne Mance, reconnais et confesse en la pre-
"sence de mon Dieu avoir receu de l'usage de ma
"main droite par les mérites de feu Monsieur Olier
"ce qui s'est passé en ceste maniere. . . . . .

"Je declare que tout ce que j'ay escrit cy-dessus
"en ces deux petites feuilles est véritable et sincère
"en foi de quoy je l'ay escrit et signé de la mesme
"main dont j'ay receu l'usage à Paris, ce 13 Fevurier,
"1659

"Jeanne Mance"

The efforts to secure additional funds for the hospital from Madame de Bullion were successful. Of the 22,000 francs obtained for the purpose, Mlle. Mance entrusted 20,000 to the care of Le Royer de la Dauversiere for the purpose of investment; but

upon his death it was found that the funds had been misappropriated, and the hospital was left without necessary means properly to carry on the work. On account of this loss, the inmates were reduced to extreme poverty, and suffered intensely from the cold and lack of nourishing food. Under such circumstances Mlle. Mance continued to administer the affairs of the hospital until 1673. After her death in that year the financial affairs of the hospital caused increasing anxiety. The income had been reduced by heavy losses to 12,000 livres a year, 400 of which were derived from the cultivation of one hundred arpents of land. Owing to the French Revolution their revenue for a time was lost altogether, but the funds were recovered in 1821.

Hôtel Dieu was destroyed by fire in 1695, in 1721, and in 1734.

During the siege of Quebec in 1759 Surgeon Robert Adair established hospitals for the British on the Island of Orleans, while the surgeons of Quebec appear to have attended to the needs of the French. Andrè Arnoux, a native of Rochfort, was surgeon-major of the French troops. He and his son established themselves on St. Louis Street near the Ursuline Convent. When Montcalm received his mortal wound on the morning of the 13th of September, he was taken to the home of the surgeon where his wounds were dressed by the younger Arnoux. It was here that Montcalm died at four o'clock on the following morning.

About the year 1773 the attention of the Government of Lower Canada was drawn to the increasing ravages of a peculiar disease, which, originating at Mal Baie, had spread to other parts of the Province. A tradition exists that it was brought to Mal Baie by a detachment of Scottish troops who were either sent there on service or had been thrown there by some accident of navigation a few years before. The great resemblance of this disorder to syphilis and its disgusting character led the unhappy sufferers who were aware of that resemblance to conceal their condition as long as possible; while those who were not aware of it looked upon the symptoms as the result of scurvy and trusted to ordinary remedies or to time for relief. From both these causes, in addition to the remoteness of the parish where the disease first made its appearance, and the want of medical assistance on the spot, the disease was not commonly known until it reached such a height as to require the attention of the Government.

The symptoms of the disease as stated in a private description circulated by the Government in 1785, are as follows:

"Ulcerations appear on the soft palate, tonsils, uvula, and mucous membrane of the mouth. As time goes on, these extend and cause destruction of these parts. At a later period nodes appear on the head, arms, legs and trunk, which, breaking down, produce extensive stinking ulceration. When the disease has attacked the nose for a length of time, it results often in the bridge falling in. Loss of the hair of the head, eyesight, and hearing, and a horrible stench are generally the precursors of death. No one is exempt from the disease, the child at the breast as well as the aged or infirm being equally attacked."

Shortly after the disease first attracted the attention of the Government in 1775, General Carleton, who was Governor at the time, sent a surgeon's mate of the Seventh Regiment to St. Paul's Bay with instructions to administer medical relief. Upon investigation the remedy which he distributed was found to consist of calomel and mercurial ointments. This officer was recalled to Quebec, and upon his death, Philippe Louis François Badelard, who came from France as Assistant-Major of the French troops, was appointed by General Haldimand, after the departure of General Carleton, to investigate the disease and report thereon. He therefore wrote a pamphlet on the subject, which was printed by the Government. It is stated that the use of the foregoing remedies resulted in many of the afflicted ones being cured.

Upon the exact nature of this disease the opinions of medical men were found to differ. Among those most keenly interested in the subject was Dr. John Bowman, who was employed by the Government in investigating the affected districts and in distributing the remedies. One Robert Jones of Montreal wrote an elaborate pamphlet, published in Montreal in 1786, to prove that the disease was not syphilis; while a letter of Dr. Charles Blake, Surgeon of H. M. Thirty-ninth Regiment, states that: "This disease is nothing more than a confirmed syphilis showing itself in different ways in different parts of the body and making anomalous symptoms and appearances accordingly. The habits of the Canadians facilitate its communication in various ways. They use the same cup, often borrow one another's pipe to smoke, chew their infants' food and spit it into their mouths. They constantly spit on their floors, and never clean them, and the lower classes are generally regardless of cleanliness. All these circumstances help to communicate the disease, which may take effect anywhere that the skin happens to be broken. The disease being of the nature already stated, it gives way to no remedy but mercury."

The Province of Quebec had as yet no facilities for teaching medicine other than the form of apprenticeship which did not appeal to the ambitious student. It was necessary, therefore, to go elsewhere for a medical education. The earliest student to go abroad was François Blanchet, who was born in 1776, and received his preliminary education at the Seminary at Quebec. At the completion of his course at the Seminary, he studied medicine in New York, and published a work on "The Application of Chemistry to Medicine." After graduation, Blanchet returned to his native home, Quebec, and entered upon the practice of his profession. His ambition, however, was not satisfied in medicine. He launched into journalism, founded a newspaper called *Le Canadien*, published several seditious articles, and was imprisoned for a short time by the haughty Governor. His active interest in politics and education, however, led to his election as a member of the legislative assembly, and it was he who proposed during his tenure of office the first law on education. During the war of 1812 he occupied the post of Chief Medical Officer in this province.

Following the example of his preceptor, Blanchet, we find Jacques Labrie, after serving his apprenticeship, going to Edinburgh to complete his course of studies. He was the first to visit and study at the Royal University there. Before leaving for Edinburgh, Labrie founded a newspaper called *Le Courier*, which announced his return to his native city in August, 1808. Like his preceptor, Labrie entered politics and became a member of the Chamber of Assembly; and it is to him and his medical colleagues that we are indebted for the institution of those tribunals which now guard the honor of the medical profession.

The condition of the medical profession and the state of education were, like everything else, in a

state of transition. The medical men of good professional status who were practising in the country at this time were either Canadians who had served their apprenticeship with a physician of standing and then gone to the mother country for graduation and further study; or they were, as often happened, Englishmen and Scotchmen who had received their entire training at home. Many of these were former army surgeons who had found the demand for their medical services in civil life so great that they had retired from active duty and were engaged only in their profession as private practitioners. It is said that the type of Englishmen who thus first practised medicine in Canada was as good as British education could make it.

On the other hand, as was natural in a country where there was no provision for medical education, and where the demand for medical assistance far exceeded the supply, quackery seems to have flourished abundantly. It was to correct such a condition of affairs that in 1750 the Intendant Bigot introduced an ordinance which may be considered the code of the medical profession in Canada. This ruling provided that no one should practice medicine without passing an examination. Those wishing to practise in a city were to be examined before the Physician of the King in the presence of the Lieutenant-Governor of the Jurisdiction. Those wishing to practise in the outlying districts were to pass an examination before the Physician of the King and a sub-delegate.

This ruling continued until 1788, when the British Parliament passed an act which provided that no one should practise physic and surgery within the Province of Quebec, or midwifery in the towns of Quebec and Montreal without a license. A license was to be obtained by passing an examination conducted by capable persons appointed by the Governor or Commander-in-Chief of the Province. This regulation did not subject those to an examination who had already taken a degree in any university, or had been commissioned as surgeons in the army or navy. "But the ordinance of 1788 had a radical fault. It placed the study and the practice of medicine absolutely in the hands of the executive power. It opened the door to partiality, to injustice and to administrative tyranny. The licenses were to be given by the Governor, and the examiners were to be nominated by the Governor also, which made them simply officers of the Government Executive. At a period when prejudice and narrow ideas in official spheres reigned, this domestication of the profession might cause serious rejection of justice.

"If one can believe the memoirs of a contemporary, this deplorable side of the ordinance soon became evident. The celebrated Pierre de Sales Laterriere, who had studied medicine for some time before leaving France, and who practised medicine from time to time since his arrival in Canada in 1766, found himself subject to the new legislation. He had practised without a diploma, often with success, according to what he says himself. But henceforth he must, under the penalty of a fine, abandon the practice of medicine or submit to an examination before the members of a bureau appointed by the Governor. He decided on the latter alternative, and was the first candidate for the study of medicine who presented himself before the Board of Medical Examiners in Canada. Let him relate his unhappy experience:

"'I had lost my certificate of St. Come, and the documents of my apprenticeship in Paris, but I knew I had talent enough to pass an examination. I was the first to present myself before the medical bureau of examination at 8 o'clock in the morning in the presence of four practitioners and four councillors, and a very large assembly attracted by curiosity because there was a new institution in the country. The examination lasted until four in the afternoon. One question did not wait for another. However correct my answers were, my examiners, because of my failure to present my letters to them, did not wish to permit me to continue practising. It was necessary for me to go to another college to obtain other certificates. Their partiality, their hardness, their malice were so apparent that many of my friends, mere spectators, said to me, 'Go to Cambridge, near Boston, where, in a short time, with the knowledge that you have obtained here, you would obtain what you now lack.' My examiners having seen that, and the reproaches that the public were making, rather through shame than friendship, said: 'Yes, if the candidate should go to Cambridge or elsewhere, we will give him a certificate favorable to the talents and knowledge which he has displayed.'"—(*Memoirs* of Pierre de Sales Laterriere.)

"During the winter and spring of 1788 M. Laterriere studied at Cambridge. After passing a satisfactory examination, in June, 1789, he obtained the diploma of Bachelor of Medicine and returned to Canada. He appeared again before the Medical Board, consisting of Drs. John Foote, James Fisher, James Davidson, Francois Lajus and Fred Oliva.

"The last clause of the Act provided that anyone holding a university degree should not be subject to an examination. Nevertheless, the examiners wished to examine him, saying that as his diploma was from a foreign university they could only give him a simple certificate of study, and could not receive him unless he passed an examination. Laterriere submitted to the examination, which he passed successfully.

"The Ordinance of 1788 relative to the Medical Profession opened the door to disadvantages of which the most serious was the arbitrariness of the executive. In proportion as the country developed, as the population increased, and as the number of candidates for medicine became greater, the acts of injustice also became more frequent. The influence of the national and political question was felt in this sphere as well as in most others. The French Canadian physicians complained that owing to official power, the English physicians made them wait and retained the exclusive authority over the administration of the profession and of the conditions of admission to the learned fraternity. It is to be noted that for about forty years there was not a single French Canadian examiner either at Quebec or Montreal."—(J. E. Roy, "Histoire du Notariat au Canada.")

This Act was repealed in 1831, when another Act was passed regulating the practice of medicine (I William 4 caput 27). This Act provided that no one should act as physician without a license from the Governor, and that all persons intending to study physic with a view to obtaining a license should undergo an examination before a *Board of Examiners* for the election of which provision was made in this Act. The Board was to consist of twelve members, seven forming a quorum.

It was also enacted that no license should be granted unless candidate were of full age and had served an apprenticeship of five years.

In 1841 an Act was passed to enable persons authorized to practise physic or surgery in Upper or Lower Canada, to practise in the Province of Canada.

By the Act of 1847 the medical profession in Lower Canada was incorporated under the name of "The College of Physicians and Surgeons of Lower Canada" and was empowered under certain restrictions to frame its own statutes for the regulation of the study of medicine in all its departments, and by-laws for its own government.

In 1849 an amendment to this Act was passed which authorized the Provincial Medical Board to issue licenses.

Let us pause to consider for a few moments what were the general conditions of the people of Nouvelle France.

During the course of time, increased intercourse with France and England had led to greater numbers of immigrants reaching the colony. The marked increase of population had brought about the prevalence of disease, "that everlasting traveller which follows humanity wherever it goes," and one of its earliest manifestations was in epidemic form.

The earliest disease to be mentioned was scurvy (mal de terre and mal de mer). A description of the symptoms and its treatment as noted by Jacques Cartier has already been given. It is interesting to note here that new and more drastic remedies were evidently resorted to. Captain Knox in his Journal writes:

"This morning I was an eye witness to the ceremony of burying a man alive, *mirabile dictu*, for the sea scurvy. To explain this matter, it must be observed that a pit was made in the ground, and the patient stood in it, with his head only above the level earth; then the mould was thrown in loose about him: and there he remained for some hours; this, I am told, is to be repeated every day until his recovery is perfected."

Scurvy, which was known in the early days of New France under the name of "Mal de terre," and later found to be the same disease as "Mal de mer," was certainly one of the chief causes which retarded the colonization of Canada. The disastrous results were seen at Tadoussac (1600), Island of St. Croix (1604-5), Port Royal (1506-9), Quebec (1609), and on the Island of Miscou (1635).

After scurvy came smallpox with its attendant train of fatalities. There were during the French regime four characteristic epidemics: 1703, 1732, 1733 and 1755.

The epidemic of 1703 was particularly severe. The registers of the Province of Quebec show that there were over two thousand deaths, Indians included. "Never had such a misery been seen," remarks the historian of the Hôtel Dieu of Quebec. "Every one was deploring the loss of a relative, one of his wife, another of her husband, one his brother, another of his children. Orphans wept for their parents; all were in tears, and there were no gatherings except for funerals."

In a letter written on 14th October, 1733, by Beauharnois to Hocquart, it is stated that "the smallpox which has afflicted this country since the end of the Autumn of 1732, up till to-day, and which has carried off nearly 2,000 persons from this colony, has exhausted the resources of everyone, and the suspension of all work has necessarily followed. The working classes at Quebec are becoming from day to day more of a burden upon men of means, and more upon us than upon others by their too frequent importunities. We cannot find any other expedient than to find work for them to take them out of their misery."

"It spread on all sides throughout this Government (Province or country) and in that of Three Rivers where it is still prevalent. By the account which has been brought to me, about 900 persons have died from this disease in the environs of Montreal, as many men as women, girls and infants. At Quebec, 278. I have not yet had a list of the number in the environments of Quebec or Three Rivers, but the number may well be five or six hundred which this disease has carried off from the colony. It is true that the greater number are children, but there have been a great number of sick at Quebec, there being at one time more than 2,000 between those in the Hôtel Dieu and in private houses.

"This disease was commonly accompanied by a circumstance which was as annoying for the sick as for those who cared for them. This was the insupportable odor which accompanied the disease. I think it will not be necessary for me to go into details. I have seen several persons attacked with this disease in France, but it was far from being as virulent as it is in Canada."

A disease as dreadful in results as smallpox naturally incited the pioneers in medicine to try various methods of treatment. We find that Michel Sarrazin thought that in his discovery of the "Sarracinea Purpurea" he had found a remedy; but this proved useless and it was not until 1765 that we find any attempt being made to introduce vaccination as a preventive. This was first employed in September, 1768, by a Mr. Latham, surgeon to the King's or Eighth Regiment of Foot, who announced to the inhabitants of Quebec that he was prepared to carry on this method of prevention.

The people of New France were indeed sorely afflicted, for we find that plague made its appearance amongst them on no less than three different occasions (1711, 1718, and 1740). The historian of Hôtel Dieu of Quebec relates that it was brought to this country by a ship hailing from Siam where the plague was prevalent about that time. The disease was therefore known as the "Disease of Siam." There are no records affording any description of the symptoms of those afflicted with the disease, hence any opinion as to the exact nature of the epidemic must be mere conjecture. The same authority, however, makes the following comments: "I have never seen so many sick in the hospital; the wards, garrets and outer buildings all were filled, and we can hardly pass between the beds. All became as black as coal as soon as they were dead." This last remark may possibly justify the opinion that the disease was what is known to-day as the "Pestis Bubonica." History also relates the recurrence of other epidemics of a similar nature, extending over several periods (1710, 1746, 1750, 1756, 1757, and 1759). The death rate was evidently very high.

Owing undoubtedly to unhygienic conditions at this time existing, diseases other than those just mentioned of an epidemic nature were prevalent amongst the colonists. Chest affections were frequent, and the methods adopted to effect a cure were perhaps unique in the history of medicine in this country. In a letter from Vaudreuil and Bégon dated at Quebec, on 6th October, 1720, we learn that "there are a great number of persons in these parts who are attacked by chest diseases, and that the most efficacious remedy is asses' milk. As there are no animals of this kind in the colonies, we beg the Council to see that a male and a female are sent out next year by the ships of His Majesty."

The use of ice for the purpose of reducing the temperature in typhoid fever is thought by many to be of comparatively recent date; but about 1780 we learn from the memoirs of Philip de Gaspé that when a child, he had been cured of a very severe

attack of typhus or typhoid fever by the use of ice. "I showed scarcely any signs of life for three days," he writes, "my death was expected each minute." So far, the patient had been treated by some one who possessed only a pretentious knowledge of medicine; as the condition of the patient became one of extreme gravity, Dr. Fred Oliva was sent for. He suggested that the child be dipped in a bath of iced water and then wrapped in hot flannels. "At the end of half an hour," writes de Gaspé, "there followed an abundant perspiration which saved my life."

From 1800 to 1832 the country appears, as far as one is able to glean from available sources, to have been singularly free from diseases of an epidemic nature. Nevertheless, Asiatic cholera, which had originated in India during the early part of the nineteenth century, gradually spread over extensive areas, until in 1832 it reached France and England. The English Government, as Christie says, "with characteristic providence and anxiety for the welfare of the province, had advised the Governor to make preparation against it in Canada, as in all probability it would with the influx of immigrants hither attend them. Legislative provision accordingly was made to meet the impending evil, and sanitary precautions were adopted. Grosse Isle, thirty miles below the port of Quebec, was made a quarantine station, to which medical men were appointed, and temporary wooden buildings were erected upon it for hospitals, and the establishment put under military authority."

The Spring of 1832 was rainy, cold and backward, and remarkable for the prevalence of heavy northeasterly gales. "With the arrival," writes Christie, "of every vessel bringing immigrants, the pestilence was expected to make its appearance in Quebec. At length, on the 8th of June, the appalling news reached the city of its actual appearance at Grosse Isle, by *The Garricks* from Dublin, with 133 passengers on board, 59 having died of cholera during the passage. From Quebec it bounded onwards as it were by leaps in its direful progress up the St. Lawrence, breaking out on the 10th at Montreal with great violence." The severity of the epidemic may be gathered from the fact that from the 9th June to the 2d September no less than 2,215 people died from this alone in the city of Quebec. Since that time, there have occurred four outbreaks (1834, 1849, 1852 and 1854) of Asiatic cholera in the Province of Quebec.

Let us now leave Quebec, with its illustrious past, and turn our attention to the city where we are now meeting which was destined to become the centre of medical education. Montreal was in 1816 a thriving town of 20,000 inhabitants, a distribution centre for immigration and the headquarters for the thriving trade of the North West Company.

The various charitable institutions of this city were for several years found inadequate to the increasing wants of the population, due to the increase of immigration. The termination of the war in 1815 brought to our shores vast numbers of persons who through sickness on their passage or poverty on their arrival were incapable of reaching their destination. Unable to procure either support or medical attendance from any funds of their own, they made an urgent appeal which prompted the benevolent inhabitants of our cities to devise means for the relief of these miserable exiles. An association of women in Montreal designated as the "Ladies' Benevolent Society" was formed expressly for the relief of the indigent immigrants; but more than this was needed. The sick required medical aid; and to attain this object, some medical men of the city agreed to give their assistance, provided a house could be obtained where the most necessitous cases of sick poor could be relieved. A small building of four apartments was then hired, and called the "House of Recovery." Small as it was, and inadequate to meet the numerous cases that needed relief, it became the germ of that noble institution which redounds so greatly to the benefit and honor of the city of Montreal—the Montreal General Hospital. This building was soon found totally inadequate to relieve all those who made request for assistance, and means were taken of raising a sum of money which, when sufficient, enabled them to rent a larger house in Craig street. The medical department was placed under the direction of four physicians who attended monthly in rotation; one of them as house surgeon attended daily in cases of accident. On the 1st May, 1819, such patients as were in the House of Recovery, together with the little property belonging to that establishment, were moved into the new institution, which now assumed the title of the "Montreal General Hospital."

Considerable interest had been aroused in favor of this newly-established charity, and to such a degree that in August, 1820, sufficient funds had been raised to enable them to buy a new site on which to erect a modern building. The site which was purchased was that which is now occupied by the hospital. On the 6th June, 1821, the foundation stone was duly laid, and in May, 1822, it was opened for the reception of patients. The medical staff consisted of Doctors Caldwell, Robertson, Holmes and Stephenson. Within ten years from the first foundation of the hospital the demands for admission exceeded its capacity, and an important addition was made to it, which was opened for the reception of patients in December, 1832. The hospital at this time contained nineteen wards and had a capacity of 160 beds."—(Hochelaga Depicta.)

An institution attended by active and energetic physicians and supplied with abundant clinical material being now a fully established fact, the staff was naturally led to approach the vexed problem of medical education. The means by which it was eventually solved have been most thoroughly described by Dr. Maude Abbott in her history of the Medical Faculty of McGill University, and from this I shall venture to quote at some length:

"The formation of a medical school was the natural outcome of a general impulse in a rapidly growing city where a real need for medical teaching exists. As a result, therefore, we find that in 1822 lectures were publicly announced and given by some of the members of the staff of the Montreal General Hospital, notably, Drs. Stephenson and Holmes. This continued for a year, when a meeting of the hospital medical staff was held on the 20th October, 1823, to consider the expediency of establishing a medical school. Steps were immediately taken to organize a teaching staff, and to utilize the hospital for clinical purposes, to give a course of lectures, and these were begun on the 15th November, 1824, and delivered at the home of the institution, the first announcement of teaching reading as follows: Principles and Practice of Medicine, Dr. Caldwell; Surgery, Anatomy and Physiology, Dr. Stephenson; Midwifery and Diseases of Children, Dr. Robertson; Chemistry, Pharmacy and Materia Medica, Dr. Holmes."

"This organization was then known as the Montreal Medical Institution, and the first session of this body was held in the Academic years 1824-5. Once established, the Montreal Medical Institution

seems to have worked its way on quickly winning good repute until 1829, which marks an epoch in its history when it became 'engrafted upon' McGill University as its medical faculty. This University, founded by the will of the Hon. James McGill, did not come into actual operation for many years, in spite of the need that was felt for such an educational institution amongst the English-speaking population. The bequest, which consisted of £10,000 and the estate of Burnside, was left in trust for a college to The Royal Institution for the Advancement of Learning, a body contemplated by a Provincial Act of 1801, but which was not incorporated and therefore not able to hold property until the year 1818. This circumstance, combined with an almost total lack of funds in the institution, delayed action. And delay was further occasioned by protracted litigation over the bequest. Indeed, had it not been for the farseeing condition of the bequest, that the legacy should revert to certain persons unless a university were established within ten years of the testator's decease, it is more than probable that the project would have been indefinitely delayed.

"In the year 1829, that portion of the lawsuit which referred to the bequest of the landed estate of Burnside was decided in favor of the University, but the question of the £10,000 continued unsettled for many years longer, and no funds were at the disposal of the college. Yet it was felt that to fulfill the conditions of the will actual teaching must now be done in the University, and the purely nominal appointments of 1823 be refilled or supplemented.

"At this time the eyes of the Royal Institution and of the friends of education were turned upon the Montreal Medical Institution, now an active teaching body of established reputation, and it was decided to bridge the difficulty by making this body the medical faculty of the University, its officers becoming professors or lecturers in their respective branches.

"On June 29, 1829, the first meeting of the Governors of "Burnside University of McGill College" was called at Burnside House, which had just come into the hands of the Royal Institution under the will. This meeting had as its object the promulgation of the Charter and the Inauguration of the University. It was largely attended by representative citizens of all classes, and at this meeting the members of the Montreal Medical Institution who had been invited to be present were formally engrafted upon the University of McGill College as its medical faculty.

"The Montreal Medical Institution, as it still continued to be called for some years, was now a faculty of an established university capable of granting degrees. For some years the only active work done in the university was that in this faculty, and by its simply fulfilling the time limit of the will, it may justly be said to have saved the university at least from much involved and tedious litigation if, indeed, it did not preserve for it the bequest itself."

The improvement of medical education was even as early as this period (1837) a much discussed subject, and relevant to it is an extremely interesting report and suggestion made by Sir John Doratt, M.D., then Inspector-General of Hospitals, who was appointed by the British Government to investigate, report upon, and advise regarding this question. In this report is suggested the establishment of a medical school in the city of Quebec in connection with Hôtel Dieu and the Marine Hospitals. These hospitals, it was considered, would conjointly provide clinical beds to the number of three hundred. The selection of Quebec for the proposed medical school was due to various reasons. The population of the city was now between 30,000 and 40,000. As the principal port also for ocean shipping, it was at Quebec that the diseases continually brought by incoming vessels and the accidents from the process of loading and unloading in port were most in evidence. It was here, therefore, that the aid of medicine and surgery was most urgently required. It was felt also that the school would attract from the colonies of New Brunswick, Nova Scotia and Prince Edward Island the young men who had hitherto been compelled to go abroad for an opportunity of studying medical science.

Among the suggestions regarding the course of medicine to be pursued was the proposed regulation that the whole period allotted for education at the medical school should be five years. The first three years were to be passed in strict attendance at the school of medicine and the last two years in close attendance to duties at the hospital. It was further suggested that the clinics at the hospital should be given from 8 to 10 A. M. These suggestions are worthy of note, since it is only within the last year that both McGill and its sister university, Laval, have adopted five years as the period necessary for the prescribed course of study. The suggestion of early clinics is now also under consideration.

The year 1826, it is to be noted in closing, marked an era in the history of medicine of the Province of Quebec: It gave birth to the first attempt which had been made with a view to opening a free intercourse with the literary world, and to promoting the interest and cultivation of medical science within the limits of our country by the formation of the first medical society in Quebec. The President was Joseph Morrin. It was at the same time that the first medical journal in the Province appeared, with the following words on the title-page: "Journal de Médecine de Québec, publié et redigé par Xavier Tessier."

The period of time allotted to the consideration of the history of medicine in our province has been covered and it remains to me now to express with the greatest of pleasure my sincerest thanks to Dr. A. G. Doughty, C.M.G., Dominion Archivist, for the privilege accorded in having access to the valuable manuscripts and works in the Archives; also for his invaluable assistance and suggestions in the preparation of this paper, and his arrangement of the bibliography; to Dr. N. E. Dionne, Librarian of the Provincial Legislature of Quebec, for his kind assistance; to Mr. C. B. Gould, Librarian of the Peter Redpath Library, McGill University, for the privilege of consulting the valuable works of reference; to his able assistant, Miss Hepburn, for her untiring energy in carrying out and preparing the research work; and to Miss Charlton, Librarian of the Medical Faculty of McGill University, for her very kind assistance.

THE PATHOGENESIS OF PERNICIOUS MALARIA.*

By WILLIAM H. DEADERICK, M.D.,

MARIANNA, ARKANSAS.

Pernicious malaria is almost as varied in pathogenesis as it is in its manifestations. Not only are its several forms associated with unlike conditions, but for the explanation of some the presence of several different factors is necessary. Thus, comatose malaria may be associated with at least two different forms of the parasite; the peripheral blood may show very great numbers of these parasites or they may be scanty; in the brain they may be found in hordes, even to the occlusion of small vessels, or they may be entirely absent.

As may be inferred no one etiological element can account for all cases, even of the same type. Probably the only essentially common factor is the presence of the malarial parasite, the manifestations of which run the gamut from the mildest intermittent to the profoundest cachexia, from the most artfully masked to the deadliest pernicious.

Until comparatively recently it was believed that infections with the so-called benign organisms never gave rise to pernicious symptoms. Celli[1] states that the tertian and quartan parasites never cause pernicious fevers. Marchiafava and Bignami[2] say that there is no instance on record of a malignant fever following tertian and quartan infections and that no autopsy has ever been made in connection with a malignant spring tertian or quartan. Mannaberg[3], Van der Scheer[4], and Maurer[5] believe that only the estivo-autumnal parasites have a rôle in the production of the pernicious fevers. Thayer, in his "Lectures on the Malarial Fevers," says that he never heard of a pernicious paroxysm occurring in tertian or quartan infections with the exception of the case of French.[6]

While the vast majority of cases of pernicious malaria are due to infection with the tropical parasites it cannot now be maintained that tertian and quartan infections are not occasionally accompanied with perniciousness. Craig[7] says that any of the malarial parasites may cause pernicious infections leading to death. Crespin[8] informs us that it is not rare to find on examination tertian and quartan parasites in these cases. Billet[9] found the large tertian in six of forty cases of typhoid pernicious. Ziemann[10] observed a case of pernicious malaria due to the benign tertian. Thiroux[11] found this parasite in a case of convulsive pernicious in a mulatto infant. Ewing[12] in sixty-four cases of the cerebral type of pernicious, found the large tertian parasite alone in five. French[6] reports a case of comatose malaria in a man, age twenty-one, whose blood harbored the tertian parasite. Hunt[13] observed a case of common tertian complicated by

*Read by title at the fifth annual meeting of the American Society of Tropical Medicine, held in Baltimore, March 28, 1908.

alarming hematemesis in a boy aged eleven. McElroy[14] had a case of comatose pernicious due to tertian infection in a negro male, aged thirty. Ficucci[15] records a case with a pernicious meningocerebellar syndrome due to tertian parasites. Fenner[16] gives the history of a case of the comatose type in an adult; the blood examination showed crescents and large tertian forms.

Craig[7] makes the assertion that quartan infections are more apt to become pernicious than tertian. The writer, however, agrees with Davidson,[17] who says that pernicious symptoms occur more rarely in connection with quartan infections than with simple tertian. The reasons for this are probably the relative rarity of quartan fever and the more even distribution of parasites throughout the circulation, there being slight tendency to form accumulations.

It is not yet known with certainty which variety of the estivo-autumnal parasite gives rise most frequently to perniciousness. Marchiafava and Bignami[2] and Mannaberg[3] hold that the tertian estivo-autumnal infections are the most dangerous, only a few cases showing the quotidian. Craig,[18] however, found the quotidian parasite most often in cases infected in Cuba and in the Philippines. This was also the experience of Wright,[19] in British Malaya, who found the pigmented quotidian parasite most frequently associated with the cerebral and gastrointestinal types of pernicious malaria.

The part played by the crescents in the pathogenesis of pernicious paroxysms is worthy of brief consideration. Marchiafava and Bignami,[20] Celli,[1] Mannaberg,[3] A. Plehn,[21] Koch,[22] Manson,[23] Thayer,[24] and others believe that this form of the organism is nonpyrogenic. Ewing,[25] however, holds with Laveran that it is by no means certain that the formation and development of the crescents are entirely innocuous to the patient. Ewing doubtless in part bases this opinion on the finding of crescents alone in thirty-three of sixty-four cases of cerebral pernicious.[12] Whether the blood examined in these cases was peripheral or visceral is not stated, but as only three were fatal it may fairly be assumed that in most instances, at least, it was peripheral. That the crescentic form of the parasite has an intimate relation to the production of the pernicious fevers is improbable for the following reasons: First, crescents alone may be found in the peripheral blood and intense localizations of active forms be present in the brain or other viscera. The number of parasites in the superficial circulation is not a reliable guide to the severity of the attack. In eleven of Ewing's sixty-four cerebral cases no parasites were fully identified, and in many of his thirty-three cases in which crescents alone were found the search was successful only after one and two hours. Secondly, crescents are rarely if ever present in the parasitic localizations and thrombi frequently observed in pernicious cases.

Of the pathogenetic factors which excite perniciousness the following are to be regarded as the most important and approximately of relatively equal importance: 1. An excessive number of parasites. 2. Localizations of parasites. 3. Toxins. 4. Individual predisposition and external etiological influences.

Number of parasites. Golgi's law, that the number of parasites determines the severity of the attack, has been generally accepted. Cases in which the parasites are in very great numbers in the peripheral blood are usually accompanied by coma.

We have no means of estimating even approximately the total number of malarial parasites in the body of a malarial patient as the distribution of the former varies within the widest limits. They may be numerous in the peripheral and visceral circulation generally; they may be scanty or absent in the peripheral circulation and numerous in most of the viscera; or they may exist in moderate numbers or be absent except in certain areas where they may be intensively localized. That the parasites are abundant, either absolutely in the body as a whole, or relatively in certain areas, probably holds good in a great majority of the cases, though, as Celli[1] states, we cannot always attribute perniciousness to the large number of parasitic forms. Marchiafava and Bignami[20] call attention to certain grave cases of comatose, convulsive, delirious or mixed pernicious in which from beginning to end and even at autopsy very few parasites are found. Mannaberg[3] says: "From the general impression which I have obtained, naturally only from the peripheral blood, the number in malignant fevers is perhaps larger, yet the difference scarcely seems so decided as to make this factor alone responsible for the perniciousness."

As applied to the number of parasites in the peripheral blood Golgi's rule is applicable only in a very general sense. Ziemann[26] states that the number of parasites in the peripheral blood is not always in direct relation to the severity of the attack. Crespin[27] acknowledges that he had difficulty in finding the parasites, which were always scanty in these cases. He gives the details of a case in which there were neither parasites nor pigment in the peripheral blood but they were numerous in the vessels of certain viscera. This writer quotes Nocht as saying "in pernicious attacks the hematozoa are not found in the peripheral blood but only in the viscera." Moore[28] says "I have often seen cases where the symptoms in no wise seemed commensurate with the number of parasites observed in the specimen of blood." According to Kendall[29] there may be only a few parasites in the peripheral circulation or it may even be impossible to find them. Mannaberg[3] states that it sometimes happens that the peripheral blood is very poor in parasites. Marchiafava and Bignami[20] note the fact that the contradiction found so often during life between the number of the parasites and the gravity of the disease disappears when an autopsy allows of an examination of all the organs. Craig[18] asserts that "the number of parasites found in the peripheral blood is not always a criterion as to the perniciousness as one of the most rapidly fatal cases I have ever observed showed but few parasites in the peripheral blood." To quote Barker[30]: "In the estivo-autumnal infections the number of organisms circulating in the peripheral parts affords, as a rule, very insufficient data upon which to base an idea of the severity of the infection." Thayer[24] says that there may be very few parasites in the peripheral circulation. He mentions a fatal case of the comatose variety showing no active parasites in the peripheral blood and only a very few ovoids and crescents after a careful search of the blood obtained by puncture of the spleen. Marchoux[31] reported three cases of pernicious malaria in which the parasites were very scanty in the peripheral circulation. Zeri[32] records four cases of pernicious fever in all of which the parasites were few in number. Bloombergh and Coffin[33] treated a case ending fatally in which no parasites could be found until forty-eight hours after onset notwithstanding repeated examinations. In seven cases in which Fenner[16] examined the blood, no parasites were found in five.

Ewing's[12] eleven cases of the comatose form in which no parasites were fully identified have been mentioned. I have observed one case of severe comatose malaria in a boy aged 12 in whose peripheral blood the parasites were scanty.

On the other hand the superficial circulation may be teeming with parasites while the patient experiences only a mild attack. Thus A. Plehn[34] gives the histories of two cases in which the symptoms were slight though the peripheral blood showed as many as thirty-five and forty-six tropical parasites respectively to each field of the microscope.

It is highly probable that an enormous number of parasites, equably distributed, depends for its power to elicit pernicious symptoms upon the increased quantity of toxin elaborated.

Localization of Parasites.—Accumulations of parasites in the brain were first described by Planer (1854) and by Frerichs (1861), those in the liver by Guarnieri (1867). More recently the minute observations of Marchiafava and Bignami, Dock, Barker, and Ewing have taught us that pernicious malaria in many of its varied manifestations is dependent on these localizations in one or more of a multiplicity of localities. Localizations in the brain have been found associated with a wide variety of cerebral symptoms; in the mucosa of the alimentary tract with gastrointestinal symptoms and typical algid attacks; in the heart with cardiac symptoms; in the medulla with bulbar paralysis; in the retina with amblyopia; in the pancreas with hemorrhagic pancreatitis, etc. In proportion to the amount of damage sustained by the kidneys in malaria there is less tendency for parasites in pernicious attacks to accumulate in these organs than in any other of the body. The most carefully studied case of this condition is that of Ewing.[35]

These localizations consist in the main of parasite-infected red blood cells; there may be, however, pigmented leucocytes and free parasites and pigment. The parasites in each particular case may be of the same or of different stages of development. The pigmented and sporulating forms are probably oftenest seen, but the earlier phases are frequently observed. It would seem reasonable that the crescents, on account of their size, would frequently form an important element in these accumulations of parasites, but such does not appear to be the case.

The cause of these parasitic concentrations is problematical. It cannot be due to the size, weight, or loss of elasticity of the infected cells, for, as Mannaberg[3] states, the benign parasites would be more apt to form thrombi if this were the cause. Kelsch and Kiener[36] and others have observed endothelial swellings in the small cerebral vessels with consequent construction of caliber, but whether this is a cause or an effect cannot be said. Vasomotor influences and phagocytosis have also been invoked in explanation. The most probable theory is that of Mannaberg[3] who attributes the condition to a sort of agglutination or adhesiveness that holds the infected erythrocytes to the vessel walls.

The symptoms present in cases in which, on post-mortem examination, localizations of parasites are demonstrated, are not always referable to these aggregations alone, since changes are frequently observed which are secondary to parasitic thrombosis and may outweigh the latter in pathogenic importance. The most conspicuous of these changes are perivascular exudation, hemorrhage, and necrosis. The hemorrhages are usually punctate, but Blanc[37] and Ziemann[26] report large cerebral clots.

This propensity of the parasites in pernicious fever to congregate undoubtedly explains the course of many cases but by no means all. Fatal cases of comatose malaria have been observed with no parasites at all in the brain. Ford[38] reports a case with serious pulmonary symptoms in which the parasites were no more numerous in the lung than in the general circulation. "The severity of the renal lesion with the absence of parasites in the renal vessels also requires mention."[39]

It is not known whether parasitic thrombi may exist without producing symptoms. Frerichs,[10] who frequently observed thrombotic occlusions of the cerebral vessels insisted that too much stress should not be laid on them on account of the rich collateral circulation. He likewise affirmed that he had more than once seen markedly pigmented brains without cerebral symptoms during life.

From the study of a case in which the patient was suddenly attacked with transient coma three times in five days, Ewing[39] believes that embolic processes are factors in some instances. This is the most probable explanation of these cases.

Toxins.—The existence of a toxin, the product of the malarial parasite, is almost universally assumed by students of malaria. The grounds for this assumption may be briefly recounted as follows:

1. An analogy with other infectious diseases.

2. Immunity. This immunity is not absolute, but that a relative immunity to malaria exists there is no room for doubt.

3. The formation of an antitoxin. Ford's[40] experiments are nothing short of conclusive of the existence of an antitoxin.

4. Degenerative changes in the kidney, liver, spleen, and other organs, not otherwise explainable.

5. Blood changes, as anemia out of proportion to the number of parasites, and brassy degeneration, stippling, and polychromatophilia of the red cells.

6. Increased toxicity of the urine and sweat.

7. The existence of coma in malaria without parasites or pigment in the brain.

8. The fever and its relation to parasitic sporulation.

9. Experimental proof. The negative results of Gualdi,[41] Montesano,[41] Mannaberg,[3] and Celli[1] are devoid of weight against the convincing experiments of Rosenau, Parker, Francis, and Beyer,[42] who demonstrated the existence in malarial blood of a poison capable of reproducing the symptoms of the disease when injected into the veins of other men.

Individual Predisposition and External Etiological Influences.—"We ought then, in cases of pernicious fever, to seek in the conditions of the ground whose quality is so different, and not in the quantity of the seed, the reason which shall explain to us the gravity of the disease."[43]

The quality of the soil, in the sense so aptly employed by Homem, as a factor in the pathogenesis of pernicious malaria, has probably not received the attention it deserves. This influence in many instances doubtless not only induces the attack but determines its type. Organs or systems enfeebled by antecedent ailments are apt to play the title rôle in the pernicious tragedy. Thus algid and choleraic attacks may be associated with a history of intestinal catarrh; the comatose and delirious cases with a history of abuse of alcohol; the convulsive with epilepsy, etc. It is not improbable that some cases of dysenteric, cardialgic, syncopal, tetanic, cataleptic, paralytic, pneumonic, pleuritic, gastralgic, and other forms described by the older writers may be similarly explained. Mercier[44] goes

so far as to say that all pernicious attacks are merely visceral complications.

Malarial subjects who are much exposed to the heat of the sun are liable to be stricken with pernicious fever, especially of the cerebral type. This danger is enhanced if to the solar heat are added fatigue, deficient or improper food, or other hardships. Certain psychic states have causative significance. Hertz[45] states that he has seen the localization of pernicious symptoms determined by injuries of the skull through a fall or a blow.

In addition to the four principal factors enumerated, congestion of viscera and parasitic obstruction of the hepatic capillaries have been regarded as important. It is probable that they have little influence.

A feeble phagocytic activity was considered by Golgi as predisposing to pernicious attacks. In the present state of our knowledge it is impossible to define the relation of this function to perniciousness.

A consideration of the relative frequency with which the several factors are concerned in the pathogenesis of the various forms of pernicious malaria will necessarily be brief. In the comatose variety any of the four chief agents may take part; idiosyncrasy and external influences may unite with any of the other factors; an extraordinary number of parasites in the general circulation without accumulation in the brain is productive of coma probably because of the toxin. Ewing[39] says that the majority of cases of comatose malaria coming to autopsy do not show a massing of parasites in the brain. He attributes these cases to general toxemia. However a study of the autopsy records of Marchiafava and Bignami[2] shows that in a great majority of their fatal comatose cases the parasites were markedly localized in the brain. Davidson[17] and Ruge[46] believe that almost always the cerebral capillaries are found filled with parasites in those who have died with coma.

Other pernicious cerebral forms are usually associated with parasitic localizations.

The algid variety, while possibly sometimes dependent on toxemia, is usually due to a massing of the parasites in the gastrointestinal mucosa. This is explained by Davidson[17] as follows: "Experiments show that the alimentary tract is in closer connection with the cardioinhibitory center than other parts of the body, and that irritation of this tract, if sufficiently powerful, will produce cardiac inhibition, with pallor of the surface and accumulation of the blood in the abdominal vessels. That the intestinal canal is the center of mischief in this form of pernicious attack will appear all the more probable if we observe the character of the disturbances so frequently associated with the algid condition—the cardialgic pain, the choleraic vomiting and purging, and the dysenteric discharges."

Other forms of pernicious malaria are probably due to localization or to complications.

AN IMPROVED TREATMENT OF GONORRHEAL ARTHRITIS (SO-CALLED GONORRHEAL RHEUMATISM).*

By EDWARD C. TITUS, M.D.,

NEW YORK.

WHILE so much has been written in late years of the therapeutic possibilities of static currents (as produced by a Wimshurst-Holz influence machine), there seems to be a general lack or knowledge as to its action on infective conditions, both local and general. Experiments extending over a series of years have led the writer to the conviction that this current exercises a potent curative influence upon such processes.

In this paper I will confine myself to presenting my observations on the action of the static currents upon one special form of infection—namely, gonorrheal arthritis, or so-called gonorrheal rheumatism. This I do because I have now collected sufficient

*Read at the II. Congrès International de Physiotherapie, at Rome, Italy, October, 1907.

clinical evidence to warrant an expression of positive views as to its therapeutic value.

A word of explanation as to how I came to employ this method in the treatment of gonorrheal arthritis may not be out of place.

For several years past, at the suggestion of Dr. William Benham Snow of New York City, I have been treating prostatitis and seminal vesiculitis of a non-gonorrheal character with the static wave current. These applications were made with a specially designed metal electrode, introduced in the rectum and placed against the prostate gland and seminal vesicles.

According to Dr. Snow's investigations, which have been completely confirmed by my own, the beneficial effect of this current in these cases is to be explained as follows: The oscillations of the static wave current, surging through the tissues at each discharge between the positive and negative poles of a Wimshurst-Holz static machine (the patient is connected to the positive pole, while the negative side is grounded), produce deep, painless, rhythmical, wave-like contractions, or physiological tissue gymnastics, even in the ultimate protoplasmic cell, thereby relieving the local stasis, inducing a circulatory drainage and restoration to normal metabolism.

Repeated experiments showed that this method of treatment, however, was of limited service in inflammatory conditions of the prostate and seminal vesicles of undoubted gonorrheal origin. It occurred to me that, by modifying the modality, it might be possible not only to produce the deep tissue contractions above mentioned, but also to induce a non-corrosive chemical action in the tissues, destructive to the gonococcus.

Without going *in extenso* into the numerous experiments made for this purpose, which might be tedious, I finally accomplished my object by the use of a specially constructed insulated vacuum electrode. I found that cases of gonorrheal prostatitis and seminal vesiculitis, which had been refractory to the application of the wave current, made with the metal electrode, improved and were ultimately cured when these vacuum tubes were employed.

This difference in action can be explained only in one way: The actinic action of the vacuum tube-discharge exerts a direct bactericidal effect upon deep-seated gonococci. In addition there are generated on the surface of the vacuum electrode, when in contact with the parts or tissues of the body, nascent nitrous acid and ozone, as a result of the disassociation of the air between the surface of the tube and the lining membrane of the part or cavity; these, together with the actinic discharge of the vacuum tube, are carried into the tissues to a depth of from 2 to 6 mm. by the action of the high-potential currents.

After becoming thoroughly convinced of the efficiency of this method in gonorrheal prostatitis, I was led to consider its possibilities in the treatment of systemic gonorrheal infection, especially that of the joints, for the following reasons. Recent investigations have been made in the laboratories of Harvard and Johns Hopkins Universities with a view of producing a serum for the treatment of gonorrheal arthritis. While these proved unsatisfactory from a therapeutic standpoint, they demonstrated that the local symptoms and tissue changes in this disease are due to the toxins of the gonococcus, and not to the local presence of the organism. It is a well-established fact that the gonococcus cannot live outside of a mucous surface. Other careful observers have determined the presence of gonococci in the prostate gland or seminal vesicles in all cases of true gonorrheal arthritis. Dr. Eugene Fuller of New York has been treating cases of chronic seminal vesiculitis by opening the vesicles through the perineal route, and curetting them thoroughly. He found, upon examining the material removed, in cases with associated chronic joint symptoms, large numbers of gonococci. Coincident with the recovery from this surgical procedure, all arthritic symptoms cleared up.

These facts seem to establish the conclusion that the gonococci are apt to persist in the prostate gland or seminal vesicles, where they thrive indefinitely, and pour out their toxins, which are taken up by the circulation and produce the usual train of symptoms of gonorrheal arthritis or general systemic infection.

How many patients would submit to a radical operation for the relief of gonorrheal rheumatism if a more simple, non-surgical means would promise the same result? Prostatic massage and stripping of the vesicles have proved ineffective, and are often harmful because of the mechanical injury frequently resulting from this plan of treatment. The plan of treatment offered here is absolutely devoid of all risk, and, when the principle is understood, will appeal to the advanced therapeutist.

In the management of this class of cases the following procedure is carried out: After the rectum has been emptied, the patient is placed in the Sims position, upon an insulated platform (this platform should be insulated by glass legs not less than 12 inches in length, and be at least three feet distant from the machine). The vacuum tube, after being lubricated, is then passed into the rectum and up against the prostate gland or seminal vesicles. The instrument is held in position by an ordinary tube-holder and stand, or the patient can hold it.

An ordinary connecting wire or rheophore is fastened to the electrode and to the negative side of the static machine. The strength of the current is determined by the length of the spark-gap between the balls of the sliding rod of the machine.

It is essential to begin with a small spark-gap and gradually increase the size according to the effect produced and the tolerance of the patient. The treatment should never be painful. A feeling of relief follows each application. Each treatment should last about twenty minutes, be repeated daily for two weeks, and then on alternate days until the secretions from the prostate and vesicles are free from gonococci, which can be determined by "stripping" the glands and examining the discharge under the microscope.

It will often be found that, during the course of and following these applications, a thick, semi-coagulated material, which consists of a wax-like, altered secretion of the glands and of dead gonococci, will be forced out of the urethra. This shows, it is fair to assume, that the action of the current not only destroys the local specific infection, but forces out the altered secretions through the natural channel by the intense cellular contraction induced.

When repeated examinations show that the secretions no longer contain gonococci, and both gland and vesicles are reduced to their normal size, attention can be directed to the joint and other tissue changes by daily application to the affected parts of indirect static sparks.

It may not be out of place to mention the assistance rendered by hygenic measures, appropriate diet, and tonics in these cases.

127 West Eleventh Street.

UNUSUAL CARDIAC MURMURS.

By RICHARD ELLIS, A.M., M.D.,

NEW YORK.

I DESIRE to describe briefly a number of unusual heart murmurs. Each has been examined by at least two physicians who have agreed in the diagnosis.

CASE I.—Cardiorespiratory murmur. From the apex to the axilla there is heard a superficial double murmur with a distinct pause between. The murmurs have the same intensity, pitch, and quality. The apex is normal; the action regular; the pulse normal, and the general health perfect. Both murmurs disappear after a deep expiration, leaving the heart sounds unusually clear.

CASE II.—Strong, well man; aged 28. To the left of the apex, and low in the axillary line, there are heard a systolic and a diastolic murmur of the same intensity, pitch, and quality. The murmurs are very clearly heard, though at times they are feeble. They are not affected by exercise or by a change in position; they entirely disappear after a full expiration.

CASE III.—Strong, well man; aged 30. Between the nipple and the sternum, there is heard a double murmur of the same intensity, pitch, and quality. The apex is normal; the action is regular. The murmurs entirely disappear after a complete expiration, as they do on forced inspiration. The murmurs are heard with their maximum intensity during normal respiration. They are short, clear puffs, lasting through the first half of the systole and the first half of the diastole. There is no murmur over the aortic area.

CASE IV.—The man is 6 feet 2 inches tall; looks anemic, but he has always been well. An unknown doctor said "diastolic murmur at the base." A careful examination by three experts shows apex in the nipple line, 5th space; some hypertrophy, but no apex murmur and no diastolic murmur. Over the pulmonic area, there is heard a loud, long systolic murmur which at times entirely disappears. The chest is somewhat flat; the sternum decidedly depressed. The murmur is evidently hemic. His physician states that he has a normal heart. The heart is sensitive, pulse 90, action regular. "Mitral regurgitation heard over the auricle" was suggested but discarded, as the murmur entirely disappeared at times. This murmur could be heard through a thick overcoat. The final judgment was—no diastolic murmur; an inconstant systolic murmur over the pulmonic area.

CASE V.—Strong, well man; aged 27. A murmur is heard, called aortic regurgitation by an outside physician. Examination shows apex normal, action regular, loud sibilant systolic murmur over the pulmonary area; murmur is quite diffused. There is no murmur heard over the mitral or aortic area. At times the murmur over the pulmonary area entirely disappears for some minutes, and then suddenly reappears. Same conditions after exercise and after lying down. Functional murmur over the pulmonic area.

CASE VI.—An unknown physician said "hypertrophy with aortic stenosis." A careful examination shows apex normal; action regular, mitral and aortic areas normal. On lying down, an unmistakable diastolic murmur is heard but no systolic murmur. On standing up, a systolic murmur is heard over the same area, exactly like the diastolic murmur. This change in the time of the murmur occurred repeatedly with the change in position. The diagnosis was a functional murmur over the pulmonic area.

CASE VII.—The lower sternum is depressed slightly, the ensiform cartilage forced to the right at an angle of 20 degrees. A clear diastolic murmur is heard along the left edge of the sternum, which entirely disappears on lying down. This was noted a number of times. The apex was normal; action regular; mitral area normal. The depressed sternum was responsible for the accidental diastolic murmur.

CASE VIII.—Man, aged 30; always well. Over the pulmonic area there is heard a short systolic murmur, followed by a short diastolic murmur of the same intensity, pitch, and quality. The murmurs continue after exercise and after lying down. There are no murmurs heard over the aortic and mitral areas: the apex is normal; the action regular. Three such cases of short systolic and "diastolic puffs" have been heard in five years of observation.

CASE IX.—Man aged 35; well in every way. Shows a double murmur as in Case No. 8, the only difference is that these murmurs are inconstant. A skilled specialist in diseases of the chest tells me he has seen two other cases like this—short functional systolic and diastolic murmurs over the pulmonic area.

CASE X.—A man aged 55; short, red, and fat. He states he has always been well. The apex is in the nipple line; the vessels are full; the heart overacting. A clear short presystolic murmur is heard with the usual palpation thrill. There is also heard that characteristic crunching thrump which indicates a mitral stenosis, even with no presystolic murmur. An experience of years proves that a mitral stenosis is most often overlooked. The average physician at once hears a faint mitral regurgitation, often hears a low aortic regurgitation, but seldom hears a mitral stenosis.

CASE XI.—A mitral stenosis with all of its typical signs. Over the left lower sternal line there is heard a clear low aortic regurgitation almost concealed by the mitral stenosis. Physicians, as a rule, are satisfied with the examination at the apex; they forget the aortic area—along the left sternal line and across the sternum to the second right and so up the right carotid.

CASE XII.—Ten years ago this man was declined by an insurance company; to-day, he reports, there are some doctors who say his heart is normal. An examination shows a presystolic murmur with a purring thrill and a characteristic crunching thrump. It is remarkable how such a heart seems "normal" to the physician who has not mastered the points of a mitral stenosis. From my own observation, I believe the crunching th-r-rump is often not recognized by some fairly good ears.

CASE XIII.—Over the mitral area there is heard a diffused systolic murmur, now clear, now faint, and now of a high pitched musical quality. This is the second inconstant clear musical high-pitched systolic squeak I have heard, associated with a constant murmur.

CASE XIV.—Man, age 36; always in good health. Over the 3d and 4th costal cartilage, left side, there is heard a long systolic murmur sounding like a mitral regurgitation. This murmur is somewhat diffused over the precordial area, but it is not heard at the apex nor at the angle of the scapula. It is not a pulmonic stenosis: it is not carried up and to the right; it is not heard over the carotid; the murmur is not changed by exercise: the apex is in the nipple line. The judgment of three physicians

was a mitral regurgitation with its maximum intensity diffused about the left auricle. This seemed to be one of those rare cases where the murmur is carried by the blood back into the left auricle.

Case XV.—Man, aged 23; looks well. There is a clear long musical systolic murmur over the aortic area with a purring thrill over the heart and over the middle of the sternum. There is also heard along the left sternal line a long, faint diastolic murmur. The apex is in the 6th space, nipple line. A marked aortic stenosis with aortic regurgitation.

Case XVI.—Man, aged 38. He has known of a "murmur" since childhood. Four physicians examined him recently, and they said they heard no murmur, but a New York specialist said "faint murmur." A careful examination with the ear alone shows a faint diastolic murmur over the lower third of the sternum and along the left sternal line. This case showed the value of training the ear to work without the stethoscope, as the faint diffused murmur was easily heard by the ear but with difficulty heard by the stethoscope. Long experience with many physicians shows the best work is done by those who depend chiefly on the ear alone in lung diseases; on the ear alone and the stethoscope in heart diseases.

Case XVII.—Man, aged 60. A well known expert had written his opinion of this case twenty years ago. The heart still remains in splendid condition; clear aortic regurgitation with regular action and normal apex.

Case XVIII.—A laboring man, aged 46, looks strong and well. Heart examination shows apex beat in the sixth space, one inch outside the nipple line, with heaving impulse and marked Corrigan pulse. There is heard a high-pitched musical churning murmur, widely diffused. The maximum intensity is heard over the middle of the sternum where the "churning" is specially clear. I have never heard such a high-pitched musical churning diastolic murmur. The man had worked daily with little inconvenience, till a failing compensation now drives him to the clinic for relief.

Case XIX.—Insurance applicant, aged 45; looks very well. Over the left sternal line there is clearly heard a systolic and a diastolic cardiorespiratory puff, somewhat diffused over the cardiac area. On deep expiration there is heard a faint long diastolic murmur along the left sternal line and across the sternum.

Case XX.—Red-faced, robust appearing man, aged 42. He had been told he has heart disease, but he states he "feels first rate and knows he will live to old age." Examination shows a huge heart with its apex two inches to the left of the nipple line; heaving action; marked Corrigan pulse; aortic second sound accentuated; good compensation. History of rheumatism for six weeks when 17 years old.

Case XXI.—A very muscular young man, aged 21; declined by an insurance company because of aortic regurgitation. At once he consulted his family doctor and returned with "blood in his eye." His doctor had told him the heart was normal. The company found the same murmur. Later, repeated examinations by three physicians disclosed this interesting condition. There was an inconstant systolic murmur, diffused about the apex, with an inconstant diastolic murmur over the aortic area, so the heart presented these four conditions: (1) no murmur; (2) systolic murmur about the apex; (3) diastolic murmur over the aortic area; (4) a systolic and a diastolic murmur. In every other way the heart was normal.

TETANUS; WITH A REPORT OF A CASE TREATED BY INTRASPINAL INJECTIONS OF MAGNESIUM SULPHATE.*

By W. H. POWERS, M.D.,

OCALA, FLA.

Tetanus is an infectious disease produced by the bacillus of tetanus, occurring in man and animals, and characterized by clonic spasms, pain, fever, constipation, etc. The bacillus of tetanus is a short, blunt-ended, spore-forming bacillus, very resistant to heat and antiseptic agents, also anaërobic. It is easily cultivated and produces perhaps several toxins which imitate all the symptoms of tetanus when introduced into the animal body. The bacillus is especially prevalent in warm climates, being found in manure heaps, the soil of gardens, street dust, etc. From its anaërobic nature it necessarily grows better in punctured wounds or wherever laceration of tissue has occurred.

Tetanus has been subdivided into several forms. The idiopathic form consists of those cases in which the history of a trauma cannot be elicited. It has a customary incubation period of from eight to fourteen days, though cases may commence before and after this period. The prognosis is considered to be influenced considerably by the term of incubation. Tyson gives a mortality of about 80 per cent. The American Text Book of Surgery gives no statistics, and others place the mortality at from 75 to 85 per cent.

There comes on rather gradually, first, a stiffness of the jaws, inability to swallow, some pain, perhaps a little elevation of temperature, constipation, rapid emaciation, clonic spasms with constant rigidity of many muscles, particularly those of the back, neck, and jaw. In most cases a history of an injury can be elicited. Profuse sweating, rapid pulse, clearness of intellect, and the recumbent position will also be noticed.

The treatment is mainly symptomatic. Necessarily, one should open the infected wound, thoroughly disinfect, nourish the patient as much as possible, keep up elimination, and, if possible, neutralize the toxins and their effects. This is accomplished by the use of antitoxin and many of the opiates, narcotics, etc. The liberated toxin, when injected into a healthy animal in suitable ascending doses, has been found to produce a potent antitoxin. This is very valuable as a preventive, and should be used in every case of suspicious wound, either in the form of the dry dusting powder or in that of the liquid antitoxin, or in both forms. Aside from this, we should use morphine, chloral, bromides, alcohol, etc., as indicated.

Case.—About the middle of December a strong, healthy negro man, while lying on a cot, was shot by another negro with a 38-caliber pistol. The ball entered the thigh muscles posteriorly about the middle of the thigh, and ranged upward, probably lodging in the hip. About ten days later he was sent to Ocala, and was seen there by Drs. Izlar and Slaughter, and myself. At this time he was having a convulsion every minute probably, belly muscles rigid, also those of the leg, thigh, back, neck, and the jaws, thus producing the risus sardonicus. He could scarcely show the tip of his tongue, and complained severely of pain, particularly in the injured leg and the abdomen. He had a slight temperature, sweating profusely, was constipated, and already showed

*Read before Florida State Medical Association April 15, 1908.

signs of emaciation. The wound of entrance was closed, and no trace of the course of the bullet was discovered, nor was any effort made to remove it, as its position was decidedly uncertain. Owing to the probable length of the bullet's course and the fact that the wound of entrance was completely healed, no effort at opening and disinfecting its tract was made, contrary to the usually indicated method. The pulse was 120 to the minute and the respiration was quickened at times, when the patient was not in a convulsion.

The diagnosis was positive and the prognosis was decidedly grave, although there could be no certainty as to the date of infection, whether at time of injury or a subsequent dressing.

The patient was chloroformed, turned on the side, with the body flexed. A small area over the lumbar vertebræ was sterilized, the line at the upper margin of innominate bones ascertained, and a little to one side of the spinous process a small skin incision was made. An ordinary solid metal 10 c.c. syringe was filled with a 25 per cent. solution of sterilized magnesium sulphate; a four-inch needle was used. After the needle had been inserted approximately to the proper place the syringe was detached. As no spinal fluid appeared, it required a little further manipulation of the needle before the cavity was penetrated. About 2 c.c. of spinal fluid was allowed to flow, then the syringe was attached and 2 c.c. of magnesium solution was injected slowly. A prescription was written for a combination of chloral, bromide, and morphine, also for a saturated solution of magnesium sulphate. This was at 4:30 P. M., and Dr. Van Hood saw the patient about 7 P. M. At this time he was having some mild convulsions. Owing to the patient being cared for by negroes, no careful account of symptoms can be given, and the medicine was also given sporadically.

On the third day, having 10 c.c. of tetanus antitoxin, I injected this deep into the thigh muscles along the supposed course of the bullet. At this time the patient was considerably worse as regards pulse and respiration, although the convulsions were not so severe as when first seen. The next day another spinal injection of magnesium sulphate was given in slightly larger dose, and three hours after this the patient was absolutely relaxed, and complained of a "splitting" headache. This injection I thought had a marked effect as late as forty-eight hours. Six days after coming to town I had the man removed to the hospital as a charity patient. At this time he was absolutely rigid, but the general conditions had improved, and the convulsions were not so frequent or severe. From this on his condition gradually improved under the use of chloral and bromide, and salts per os, until sixteen days after his arrival in town, when he was able to walk about.

Remarks.—A contracted muscle means a working muscle, and constant contraction means constant work, therefore, exhaustion, and this is given as the cause of death in tetanus. The intraspinal use of magnesium sulphate paralyzes the muscles, therefore gives rest while the system is elaborating an antitoxin. No mortality from this procedure has been recorded either in the few cases in which injections of magnesium sulphate have been used or in experimental work upon animals.

The injection itself is comparatively simple. The solution should be used only at body temperature. The injection should be repeated at intervals of from twenty-four to seventy-two hours, depending upon the severity of the seizures.

Pathological Physiology and Motor Reduction of Visceral Symptoms of Tabetics.—Maurice Faure, in a paper read before the Ninth French Medical Congress, says that the muscles of the life of nutrition are disturbed in their function in tabetics in the same order and from the same causes as those of the life of relation—that is: 1. A lessened tonicity (atony, hypotonia, relaxation). 2. A diminution or disappearance of coordination. These visceral symptoms depend on the medullary and radicular lesions that exist (laryngeal, visceral, intestinal). Atony or relaxation of the muscular tunics of the bladder, intestine, or bronchial walls, determines stasis and infection of these physiological reservoirs. These muscles, not being under the control of the will, their reduction is impossible, but massage and faradization excite their contractility and diminish their atony. The voluntary cervical muscles, the scapular, dorsal, and intercostal muscles, the diaphragm, the walls of the abdomen, and the perineal floor, are all, like the muscles of the limbs, subject to atony and incoordination. Their atony results in lessening of the resistance of the abdominal and thoracic walls, the diaphragm, and the perineum. Consequently, when the thorax dilates in the inspiratory effort, when the diaphragm compresses the intestinal masses for the effort of expulsion of the urine and feces, the walls of the thorax and abdomen allow themselves to be distended, the diaphragm is aspirated into the thorax, and the pressure in the interior of these cavities is unchanged. There result from this insufficient variations of pressure corresponding to respiration, micturition, defecation, and stasis of the mucus, urine, and feces, which produce insufficient nutrition, infection, and cachexia. This incoordination has, as a result, a defect of synergy in contraction. When the thorax contracts in respiration or coughing, the glottis closes instead of opening; when the abdominal wall contracts for defecation the diaphragm and perineum relax; when the urine is about to flow from the bladder the striped muscles of the sphincter and perineum do not contract to arrest it, etc. From this result laryngeal crises, retention or incontinence of urine and feces, etc. The functions of the life of nutrition are, from a motor point of view, submitted to education like the functions of the life of relation (gymnastic education of the act of respiration, social education of micturition, and defecation). It is possible to teach again these mechanisms as one learns again the mechanism of walking. These exercises are adapted to the action of the muscles of the neck, thorax, abdomen, and perineum, which are submitted to the general laws of motor reduction. Laryngeal crises may thus be quickly lessened or prevented; subjects that were obliged to make use of the catheter recover the power of voluntary micturition; defecation becomes easy, and constipation less; infections of the bladder, intestine, and bronchial tubes are prevented or lessened, and the principal dangers that threaten the tabetic are thus removed.

Purulent Pleurisy of the Apex.—G. Carrière and J. Vanverts state that pleurisy of the apex of a purulent type is rare, since the anatomical situation of the apex allows pus to gravitate, and it can only remain at the apex when adhesions confine it there. The retracted and adherent lung forms the floor of the containing cavity. The pus is at first confined, and gives the symptoms of fever, general malaise, dilatation of the interspaces, and loss of vesicular murmur. Later it may open spontaneously, and all the symptoms subside, expectoration becoming very abundant. A pleurobronchial opening may be established, and cicatrization and closure of the pocket result in a cure. Exceptionally, it opens through an intercostal space. Opening gives immediate relief to the general symptoms. The treatment demands surgical opening of the purulent cavity and its drainage if opened. It involves washing out with antiseptics when the cavity is already open.—*Le Nord Médical.*

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, July 25, 1908.

IN QUEST OF LONGEVITY.

IT is a matter of some significance that during the past six months there have been published three volumes dealing with the special problem of lengthening the span of human life through a minute scientific study of the causes of old age and death. To be sure, the desire for immortality is very old, much older even than Plato or any of his teachers, who strove to determine the nature and characteristics of soul rather than of body, but all the scientific efforts that have been made to show why old age comes on apace have up to the present failed to satisfy the inquiring mind. That "all men would live long, but no man would be old" is an epigram that comes back to us from first-reader days. Its author is long since dead and forgotten, yet the truth of his statement lives on in the minds and hearts of us all.

Through the zeal of Metchnikoff, whose "Prolongation of Life" is enjoying as wide a reading in this country as it obtained when first published in France two years ago, we are brought face to face with an analysis of the problems of disease, old age, and death. Whether Metchnikoff's theory of intestinal infection and systemic absorption as a cause of premature decay be correct or not, it is of vital interest at the present moment, inasmuch as we are just beginning to realize the evil results of autointoxication and the importance of the digestive tract as a factor in diseases of obscure origin. We have been taught to believe and accept as indisputable that the "fatal triad" is inseparable from our common earthly lives; but, however it may be with old age and death, we have learned to know that disease is largely a matter of accident, dependent upon ignorance, and that under ideal sanitary conditions most diseases would disappear from the face of the earth forever. But we are still far from the ideal, for, with the great increase of population, there has come to be a great increase in the chances of accidental death through the multiplication of disease germs and the possibilities of ready transmission from host to host.

Present-day records tend to show that the average length of life in rural districts is greater than in large cities, taking into account the factors of heredity, exposure to the elements, etc., and every surgeon knows how much more free his country patients are from wound infection than are those in his city practice. These matters have been touched upon by Dr. Pearce Kintzing, in his recent book on "Long Life and How to Attain It," and, although the author is an avowed lover of rural life, and is, perhaps, prejudiced in favor of the field and wood, there is much truth in what he says, and not a little mental pabulum for the urbanite who sometimes thinks of the country only as a group of white slabs surrounded by a fence. However, since Dr. Kintzing writes from a popular viewpoint, and not distinctively for the profession, his book will scarcely have a wide appeal for medical men who are familiar with the principle of practical hygiene.

In his book on "Age, Growth, and Death," also recently published, Prof. C. S. Minot of Harvard University takes up the matter as an embryologist, who holds that the forces leading to old age are active even at birth. Life or the power of assimilation upon which it depends is like a top set spinning by a boy; it runs occasionally for a long time, if a proper impetus has been given it, but it runs with ever decreasing force and rapidity—and finally runs down. We obtain, therefore, in this book points of view which suggest new lines for future investigators.

There is much to be said in support of the thesis that we are still almost totally ignorant of the workings of great cosmogonic forces, as they move to and fro and weave into a complete fabric the threads of human destiny. We do not know, perhaps never can know, what life *is*, because we are obliged to be eternally concerned with what life *does*. When a patient dies we are content to insert typhoid or tuberculosis in his death certificate, inasmuch as this satisfies the law, but carried back to the last analysis we are not quite sure that we know what was the real cause of the cessation of life, because we are circumscribed by the complexities of nature that lie thick everywhere about us.

THE PROGNOSIS OF SYPHILIS.

THE general prognosis of syphilis is, of course, well known to physicians, this aspect of the ancient disease having been studied through the many centuries of its existence. Careful statistics of the subsequent histories of patients are not, however, easily obtained in numbers large enough for generalizations, especially in the United States, where the absence of the passport system makes it difficult to trace a man very far if he has several times changed his residence. The police regulations of Germany are quite different in this respect, and it is such regulations that have enabled Waldvogel and Süssenguth to compile the data referring to 297 patients treated for syphilis in the Göttingen Clinic between 1873 and 1882. The results are of interest in one respect at least: evil consequences have not at all been as frequent in this series of cases as is usually thought to be the rule by both medical and lay men. No predisposition to tuberculosis seems to have followed syphilitic infection, the number of deaths from this cause being less than the one in three which is the usual rate of mortality from it, according to the data of the German Health Office. Seven patients were affected with tabes dorsalis, and three of them died from this disease. Eleven deaths, or 9.3 per cent. of the total 118 deaths, were due to progressive paralysis, three other patients being still alive, though suffering from this supposed sequel of syphilis. The general mortality of the patients

when compared with the life insurance figures for the proper age appeared to be higher by 9 per cent.; moreover, the average loss of life expectation was two years per person. Almost none of the patients gave any history of tertiary symptoms, and at least 109 of the 297 patients recovered good health after the treatment, consisting in inunctions, and sometimes in injections, of mercuric preparations, while another dozen were suffering from various heart, kidney, and lung lesions that could not be looked upon as resulting from the old syphilitic infection.

So far as the immediate victims of specific disease are concerned, these figures little justify the usual view of luetic infection as carrying with it a greatly increased morbidity and mortality. The disease, however, is especially characterized by the damage it does to the descendants of the patients, and the authors whose work we are considering have tried to obtain some data of this aspect of the subject. Of the 265 patients with secondary symptoms, 48 remained single, a percentage which is quite high, considering the rural character of the population treated. The marriages, however, did not seem to have been any less fruitful than the average shown by life statistics. Further figures in reference to other points involved could not be obtained or were based on too few cases to be of general application. One thing seems to be shown by the careful statistical tables of the authors: so far as the material studied by them is concerned, syphilis is no such fateful disease as is usually thought. The comparison with the results of the same infection among town dwellers, as well as the influence of race and country upon the prognosis, would well repay the trouble of anyone who has sufficient material open to him for such a study.

Nonparasitic Chyluria.

The parasite responsible for elephantiasis and chyluria of the tropical and subtropical regions, *Filaria bancrofti,* is widely distributed in China, India, Africa, Brazil, and elsewhere, and the inhabitants of these countries or travelers through them often turn up in the north with the above symptoms. The history in such cases points directly, of course, to infection with the parasite as the cause of the disease. But in addition to these parasitic cases, medical literature contains a few reports of chyluria occurring in persons who have never left northern countries, and, indeed, have in no way exposed themselves to infection with filaria. The ingenuity of the physician observing the case is then taxed to find some plausible explanation for the unusual condition. Osler tells of the postmortem in a case of thirteen years' duration, in which no trace of the parasite could be found (Practice of Medicine), and in the *Münchener medizinische Wochenschrift* for June 30, 1908, Dr. Herman Lüdke reports a case of chyluria in a woman who had never left Southern Germany. In this patient a severe cholecystitis, due to the infection with the colon bacillus, was followed by the appearance of chyluria; the urine contained sugar, albumin of several types, and a great deal of fat, which was responsible for the milky appearance and the similarity of the fluid to chyle. The change of diet to fat-free substances seemed to have no effect upon the fat-content of the urine, which reached six to eight grams of fat to the liter; just as little effect in the opposite direction was noted when a diet rich in fatty foodstuffs was ordered. No treatment seemed effective, nor was the condition any more serious for the patient than a moderate glucosuria, which is so often observed to continue for many years and is quite compatible with average good health. The only pathological condition which could be thought of in connection with the etiology in this case of chyluria was, of course, the severe cystitis, for no exposure to a parasite of the filaria type was present in the case and no trace of such infection could be found on repeated examinations. Excess of chyle in the blood was also absent, the examination for such a chylemia proving completely negative. The only explanation, then, was that the long-continued inflammation of the bladder might have produced some lesion of the lymphatics which allowed the admixture of the chyle to the urine. This cause appears probable in the case reported, but no such bladder lesion has been found in other patients suffering from the nonparasitic form of this affection, and an acceptable explanation of the condition in such cases is still to be found.

Ophthalmoreaction in Typhoid Fever.

We have already noted the application which Chantemesse made of the recent methods of diagnosing tuberculosis by the local reaction produced in the conjunctiva to the diagnosis of typhoid fever. Since the appearance of his report Kraus, Lusenberger, and Russ have published their results with the method employed by him, which in no way corroborate his findings. However, they used slightly different preparations of the toxin of typhoid fever, while Orszag, who followed the technique of Chantemesse, obtained results which were much more in accord with the latter's observations. Dr. Meroni has gone over the ground once more and in the *Münchener medizinische Wochenschrift* for June 30, 1908, reports the data obtained by testing twenty-four typhoid patients with the toxin instillations. In all of them positive reaction could be noted, of varying severity and duration, but always well enough marked to serve as a sign of some importance in the diagnosis of the disease. Control experiments showed that the reaction was sufficiently specific for typhoid fever if it continued twenty-four hours after the instillation; no ill-effects whatever were noted; the technique of Chantemesse proved to be quite reliable, and it is simple enough to deserve trial in the hands of other observers. The test has aroused no such widespread interest as the similar reactions in tuberculosis, but its importance is such that further results will be looked for by all practical physicians who appreciate the difficulties of diagnosing typhoid fever in places where bacteriological methods cannot be applied for this purpose.

The Relation of the Ear Lobule to Tuberculosis.

None of the numerous degeneration stigmata have been so much discussed as anomalies of the ear. While investigating the relation of tuberculosis to nervous and mental diseases Rossolino (*Wiener klinische Wochenschrift,* No. 22, 1908) noticed a peculiar shape of the ear in a large percentage of the patients who gave either a family history of tuberculosis or showed a habitus phthisicus. In the examination of 800 patients he found 531 who gave a tuberculous family history or displayed the

habitus phthisicus, and seventy-six per cent. of these showed abnormalities of the ears, chiefly an attachment of the lobule. Only twenty per cent. of the remaining 269 showed any degenerative changes in the ears. That an alcoholic or psychopathic family history did not influence the ears is shown by the fact that patients with such a family history, but not having the habitus phthisicus or giving a tuberculous family history, showed normal ears in eighty per cent. of the cases. Furthermore, patients with either a tuberculous habitus or a family history of the disease, and with no alcoholic or psychopathic family history, showed degenerated ears in eighty-three per cent. of the cases. If what Rossolino says is true, some relation must exist between the tuberculous habitus and anomalies of the ear lobule. His view, however, differs from that of the anthropologists who hold that the anomalies of the ear are not signs of degeneration but racial characteristics. Possibly both are right, for a large majority of the Chinese have the so-called Mongolian ear and at the same time are a race not well capable of resisting disease. Mense claims that the negro frequently presents abnormal conditions of the ear and he is certainly prone to tuberculosis.

Misuse of the Red Cross Emblem.

The Secretary of the New York State Branch of the Red Cross protests against the use of the Geneva or red cross as a means of raising funds for hospitals on "tag days" and similar occasions. The red cross is the common symbol of all army hospital corps and auxiliary Red Cross societies, which protects the sick and injured and the hospital personnel from attacks in time of war, and, the world over, has come to signify this special and official kind of protection, relief, and prevention of sickness and injury in war, disaster, and pestilence. Its employment except in this connection must seriously impair its usefulness. The need of a symbol to summarize and recall to the popular mind what has been done along these lines and what remains to be done is plain, and the Red Cross feels it necessary to protect its emblem, misuse of which was made a misdemeanor by an Act of Congress, January 5, 1905. The Department of Charities of New York City and Bellevue and the Allied Hospitals have set a good example by changing from the red cross to the symbol of Esculapius, an example which has already been followed to some extent. The national Red Cross is not a private society; anyone may become a member and have a voice; it is public and official; and the finances are audited by the War Department. It is linked with the Red Cross societies of forty-two other nations, whose total membership is upward of five million. In part as a preparation for such emergency relief as it may at any time be called upon to give, the Red Cross has this year taken up the mission of combating tuberculosis, which slays its hundreds where war slays its tens. Preparation is a matter of educating and arousing the people, and millions of dollars are needed before a condition of preparedness can be reached. In all this work the advantage of a distinct and peculiar emblem to signify the work of the Red Cross is evident.

A New Pathogenic Bacillus.

Great wars and great pestilences are no longer as synchronous as they were wont to be in former days, when the modern sanitary precautions in time of war were unknown. However, large congregations of men exposed in many ways to infections even now serve as splendid material for the study of diseases spread by contact or by food and utensils, and the Japanese physicians have made good use of the opportunity which the recent Russo-Japanese war offered them. Horiuchi reports in the *Centralblatt für Bakteriologie, etc.*, for May 16, 1908, the results of a study of a peculiar disease which attacked many soldiers. It was characterized by a sudden onset with a distinct chill: a high, continuous temperature; an exanthem appearing on the third to the fifth day of the disease; a step-like temperature curve during defervescence, and the absence of the Widal agglutination phenomenon. Horiuchi succeeded in isolating a bacillus from the blood of the spleen and of the veins, which agglutinated with the blood serum of the patients and possessed perfectly distinct and peculiar cultural characteristics. The new organism proved to be quite pathogenic for mice, guinea pigs, and rabbits. The author proposes to call it the bacillus of Manchurian exanthematic fever, for, although the disease observed by him has much in common with typhus fever, yet it may not be identical with it.

News of the Week.

Help for the Babies.—The Illinois State Board of Health has reissued its excellent pamphlet on the Care of the Baby. The pamphlet is well illustrated and most important teachings, tersely put, are displayed in bold-faced type. Sound information as to the importance of breast feeding is given, as well as directions in detail for preparing milk for children not breast-fed. The need of cleanliness both for the baby and for the mother, as well as for all articles used in preparing food, is insisted upon: and suggestions for dressing the baby lightly and comfortably during the summer are given. Dairymen and milk dealers are well instructed in a short chapter, and the pamphlet closes with a list of disinfectants.

Under the general direction of the Brooklyn Children's Aid Society, a number of the relief associations of that city have begun to work on a cooperative plan for saving the lives of the babies. The city has been divided into districts, and the Department of Health has assigned trained nurses to work in them. Sixteen stations for distributing modified milk have also been established, and medicines will be furnished free of charge. In New York, the number of deaths among infants during the hot weather recently has caused renewed efforts for their protection, and the attempt is being made to educate the mothers by systematic visits of trained nurses.

The Public Health and Marine-Hospital Service.—Candidates for admission to the grade of assistant surgeon in the Public Health and Marine-Hospital Service will be examined in Washington on September 14, 1908. Candidates must be between 22 and 30 years of age, and graduates of a reputable medical college. The examinations will be physical, oral, written, and clinical. Upon appointment, assignment is usually made first to one of the large hospitals. After four years' service, assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon; promotion to the grade of surgeon is made according to seniority and after due examination. Assistant surgeons receive $1,600, passed assistant surgeons $2,000, surgeons $2,500 per year, and are

entitled to furnished quarters for themselves and their families or to allowance for the same. Further information may be obtained on application to the Surgeon-General, Public Health and Marine-Hospital Service, Washington, D. C.

China Bars Morphine.—Japan has now been asked to join the other powers in consenting to the restriction of the importation of morphine into China, as well as of instruments used for injecting the drug. Measures for the control of the traffic are to be discussed at a congress which will meet in Shanghai next January. Unless Japan gives her consent, China is helpless to restrict the importation of the drug.

Opium in the Philippines.—The report of the Board of Health for the Philippine Islands states that since March 1, 1908, when the prohibition of the use of opium except for medical and scientific purposes, became absolute, the number of opium habitués desiring hospital treatment has enormously increased. Of the 307 patients admitted to San Lazaro, 260 have been discharged as cured. The majority seem to be really anxious to be relieved.

Absinthe Tabooed.—The question of prohibiting the manufacture and sale of absinthe in Switzerland having been put before the people, a vote of 80,000 majority in favor of the prohibition has been recorded. In France, a circular signed by 114 of the 300 Senators has been issued, proposing the passage of a bill making the manufacture of absinthe a crime.

United States Mails Will Not Carry Cocaine.—Government reports having shown that an enormous amount of cocaine is sent through the mails each year, the Post Office Department on July 16 issued an order denying the use of the mails to cocaine or its derivatives. Patent medicines containing the drug are included in the prohibition. The crusades carried on in many of the cities against the sale of the drug have caused the users to obtain it directly from the manufacturers through the mails, and the ease with which it has been obtained has largely negatived the work in combating the evil. The habit has said to have fixed itself to an alarming extent upon the negroes, especially of the South, and to offer as great a menace to the peace of that section of the country as the liquor habit. It is distributed among them largely by peddlers, who sell the powder by the "card"; that is, he measures it by spreading it thinly over the spots on a playing card. A customer may purchase anything from a "deuce" to a "ten spot" of "coke." A number of patent remedies said to contain cocaine are now being investigated by the Bureau of Chemistry of the Department of Agriculture.

Scarlet Fever in New York.—The records of the Willard Parker Hospital show that during the spring there was a large increase in the number of cases of scarlet fever in New York. In March of this year, for example, there were 405 more cases than in the same month of 1907. On April 25, the hospital, which has accommodations for 220 such patients, sheltered 646. Up to July 1, 1,500 cases had been received. An addition to the hospital building is urgently needed.

Yellow Fever in Cuba.—An outbreak of yellow fever has been reported from Daiquiri, Province of Santiago, Cuba. Ten cases have occurred.

Plague in Venezuela.—Reports from Caracas state that the epidemic of plague in Venezuela is abating. No new cases have developed in Caracas since June 28, and the last death from the disease in La Guayra occurred on June 28. Officially, the epidemic in La Guayra ended on July 3.

School of Preventive Medicine.—The State Health Commissioner has announced that arrangements have been made to establish a school of sanitary science and preventive medicine at Cornell University. The course will open on October 8, and lecturers have been appointed from the university faculty and from the staff of the State Board of Health. Lectures on special topics in sanitary engineering will also be given by specialists.

Wall Street Tackles Phthisis.—The three hundred telephone clerks employed by the New York Stock Exchange are being examined by a physician of the Health Department for tuberculosis. Of the thirty examined on the first day, three were found to be affected, and their employers at once undertook to provide suitable treatment for them. A short time ago all the employees, with the exception of the telephone operators, were examined, and of the four hundred, three were found with tuberculosis and were sent to a sanatorium by the Governing Board of the Exchange.

Preaching the Crusade Against Tuberculosis.—The clergymen of nine churches in Memphis gave up their pulpits on Sunday last to physicians and others interested in the warfare against tuberculosis, who detailed the work that was being done in this direction and urged their hearers to join in the crusade. It is estimated that over five thousand persons were appealed to directly in this manner, while the attention of thousands of others was called to the subject by the newspaper accounts of the novel procedure.

University Bars Tuberculosis.—The University of Utah has promulgated a decree denying admission to classrooms of the institution to any teacher, student, or employee suffering from tuberculosis.

Drinking Water on Trains.—The New York State Department of Health has recently investigated the sources of the drinking water provided for passengers by the railroads operating in the State. From the returns, it may be said that the quality of the water corresponds to that of the water used in the larger cities and towns. The department has been able to recommend certain changes in the source of supply where this was known to be unsatisfactory. In several instances a special and presumably better supply of water is provided for the dining cars.

Pasteurization in Vienna.—A complete plant for pasteurizing milk has been presented to Vienna by Mr. Nathan Straus of New York, and formally accepted by the Minister of the Interior. The rate of infant mortality in Vienna is high, and the workings of the plant will be followed with particular interest.

New Diet Kitchen.—The New York Diet Kitchen Association opened this week another station in the chain it already maintains in the tenement districts for supplying clean milk and fresh eggs to the sick poor. The new kitchen is located on the upper west side, and is the eighth to be opened. During the month of June these stations gave out 25,810 quarts of certified milk in cases of actual need, and during the recent very severe hot weather not a single death occurred among babies who were being fed upon this milk. The first diet kitchen of the Association was opened in 1873, in connection with the Demilt Dispensary.

New York Hospital System.—The State Charities Aid Association has issued a supplementary report on the hospital system of the city making recommendation for changes and additions. Emergency relief stations with an ambulance service

attached are recommended for establishment for the better treatment of rush cases. Local hospitals on the general lines of those already existing, but for acute cases and with special vacant wards for the handling of cases following great accidents, are also recommended. In addition to these, it is thought there should be hospitals for subacute and chronic diseases, for tuberculosis, and for acute contagious diseases. With such a system, New York would naturally become a great center for medical study and education. It is contended that hospitals should be built, as far as possible, in the crowded centers, where they would be most accessible. At present the daily number of sick in the entire city is estimated at 135,396. Of every 100 in the population 2.21 are sick of chronic or acute disease, and of these 8.4 per cent. are treated in hospitals. A more general treatment of cases in hospitals would, it is thought, materially lower the death rate.

Germs in Cracked Dishes.—Dr. Wiley of the Bureau of Chemistry of the Department of Agriculture, has extended the investigations of the Bureau to include the examination of cracked dishes taken from some of the "quick lunch" rooms of Washington. Lurking in the seams and cracks twenty-five different species of organisms were discovered by the bacteriologist of the department, a large number of them belonging to the colon group. In spite of the spotless appearance of the kitchens of some of these places, Dr. Wiley holds there is danger from them, since it is impossible to clean cracked dishes properly. The conditions found in Washington could doubtless be duplicated in any large city, and are probably of little importance in the dissemination of disease.

Girls Healthier than Boys.—Interesting facts have been presented as the result of the examination, under the new Child Labor Law of the District of Columbia, of 1,700 children, boys and girls, under sixteen years of age, who desire permits to go to work. Of this number, 75 boys were refused permits, and but 2 girls. Diseases of the heart and lungs were given as the reason for the majority of the rejections. As a consequence, it is stated that girls between the ages of twelve and sixteen are far better able to battle with the world than are their brothers.

Death of a Centenarian.—Within one month of her 105th birthday, Mrs. Sarah Hall Doremus died on July 15, at her home in Newark. Born in New Jersey, she has lived there all her life, and had been in good health until three months ago. With the exception of Washington, she had lived during the term of every President of the United States.

Provision for Treatment of Rabies.—The Secretary of the Illinois State Board of Health announces that in 1905 the General Assembly made provision for the care and treatment of poor persons duly certified by regular physicians who have been bitten by rabid animals, or otherwise put in danger of infection from rabies, and that such persons, unable to pay for treatment themselves, would be cared for at the expense of the State at the Pasteur Institute, Chicago.

Christian Science Deaths.—The recent deaths in New Jersey of two persons under Christian Science treatment, have brought about the appointment by the President of the Bergen County Medical Society of a committee of investigation. The chairman, Dr. J. Finley Bell of Englewood, in a very timely statement, calls attention to the fact that these "healers," knowing nothing of medicine, science, anatomy, or anything else that might tend to aid in relieving the suffering of the sick, get good pay for their attendance, and yet declare they do not practise medicine because no drugs are administered, and are, therefore, not subject to the law. Dr. Bell calls for a revision of the law, if necessary, to put a stop to these illegal practices.

Dr. George Dock, Professor of the Practice of Medicine in the University of Michigan, has been elected to the Chair of the Theory and Practice of Medicine in the Medical Department of Tulane University of Louisiana.

Dr. Daniel N. Eisendrath has been elected Professor of Surgery in the College of Physicians and Surgeons, Medical Department of the University of Illinois.

Drs. Alfred D. Kohn and Alexander L. Blackwood were recently appointed members of the Board of Education of Chicago.

New Journals.—The *Southern Medical Journal* makes its first appearance with a July number, under the editorship of Dr. J. A. Witherspoon of Nashville, Tenn., and a large staff of assistants and collaborators. The issue contains, besides case reports, a number of original articles, among them, "Clinical Notes on Apoplexy," by E. G. Wood; "Diagnosis of Painful Feet," by E. L. Scott; "Recent Work on Stomach Digestion," by W. H. Witt, and "Goiters of the Young," by Charles H. Mayo. The journal presents a very attractive appearance.

School Hygiene is the name of a new monthly issued in Boston by the American School Hygiene Association. The journal is of convenient size and good type. Abstracts of papers on eyestrain in school children, school baths in Sweden, the prevention of tuberculosis in school children, and the demands of school hygiene, are given. There are also short articles on "Playground Legislation," "The Education of the Public in Scientific Medicine," and "School Clinics." The article by Dr. Jarrett on the health of school children, in a recent issue of the MEDICAL RECORD, is reviewed at length.

The *Journal of the Tennessee State Medical Association* appeared in June for the first time. A report of the seventy-fifth annual meeting of the Association is included, as well as the address by the President, Dr. A. B. Cooke, on "Medical Organization: Its Purposes and Possibilities." The journal is of octavo size, with good paper and print, and makes a pleasing appearance.

Fasted Fifty-six Days.—Unable to obtain a physician because of the ban upon her husband, the wife of the "Outlaw of Cameron Dam," Wisconsin, has succeeded, according to newspaper reports, in curing herself of appendicitis by fasting fifty-six days. She is said to have lost sixty pounds in addition to the appendicitis.

The Fifth Pan-American Medical Congress will be opened in a formal way by the President of the Republic of Guatemala on the evening of August 5, at which session the official representatives of the country and those of the other American Republics will be present. The titles of the papers received, as well as anything else of importance, will be made known by the Secretary-General. There will also be an intermediate and a closing session, in the latter of which representatives of the different countries will make farewell speeches, and the congress will be duly closed. In the intermediate session, there will be scientific works presented, but there will be no discussions. The various section meetings will begin on the morning of the 7th, and continue until the congress adjourns. The papers are principally upon questions of general and tropical medicine,

hygiene and sanitation, both of civil and military character, and general surgery, the consideration of the different remedial agents used in southern countries, and papers on the different specialties. The papers from the United States cover about the same subjects, in addition to which there are a number to be presented on the different specialties. There are twenty sections, but the probabilities are that the number will be reduced to four or five, in order to insure a better attendance. There will probably be a section in medicine, including general, internal, and tropical medicine, with perhaps children's diseases, nervous and mental diseases, and therapeutics; a surgical section, including general and abdominal surgery, gynecology, anatomy, and obstetrics; a section on eye, ear, nose, and throat diseases; a section in hygiene, demography, miltary sanitation, and epidemiology. The entertainments will consist of a banquet in honor of the congressists, a ball also in their honor, a mock battle, a horse race, and numerous excursions to different points of interest.

British Medical Association.—The seventy-eighth annual meeting of the Association will be held at Sheffield, July 24 to 31, under the presidency of Dr. Henry Davy. The President-elect is Mr. Simeon Snell of Sheffield. The address in medicine will be delivered by Dr. James Kingston Fowler, the address in surgery by Mr. Rutherford John Pye-Smith, and the popular lecture on "Dust and Disease" by Mr. Edmund Owen.

South Dakota Board of Medical Examiners.—At the regular meeting of this Board in Deadwood, July 8 and 9, there was thirty-five applicants for a license to practice, thirty-one of whom passed. The annual election of officers of the Board resulted as follows: *President,* L. G. Hill of Watertown; *Vice-President,* H. S. Graves of Hurley; *Secretary and Treasurer,* H. E. McNutt of Aberdeen (reelected).

South Side Branch of the Chicago Medical Society.—The annual meeting was held June 19, when Dr. Edwin B. Tuteur was elected *President,* and Dr. F. Gurney Stubbs, *Secretary.*

Obituary Notes.—Dr. William Monroe of Monroe, Wis., the oldest practitioner of that State, died on July 6, following a paralytic stroke, at the age of 90 years. Dr. Monroe was graduated from Rush Medical College, Chicago, about 1865.

Dr. Beatrice Curran of South Hadley Falls, Mass., died suddenly at her home on July 9, at the age of 26 years. Dr. Curran was graduated from the Woman's Medical College of Philadelphia in 1904, and for a year or so practised in that city.

Dr. Samuel C. Primrose of Lawrencetown, Nova Scotia, died on July 1, after a long illness, at the age of 71 years.

Dr. Frank H. Montgomery of Chicago was drowned while sailing on Lake Michigan on July 14, aged 46 years. Dr. Montgomery was graduated from Rush Medical College in 1888, and had for some time filled the position of associate professor of disease of the skin at the same college. He was attending dermatologist to a number of hospitals, and had published the results of his work on diseases of the skin, and on syphilis and other venereal diseases.

Dr. William Elmer of Trenton, N. J., died on July 18, at Atlantic City, after a long illness, aged 68 years. He was graduated from the Medical Department of the University of Pennsylvania in 1864, and was a member of the American Medical Association, an ex-President of the New Jersey Medical Society, and Medical Director of the Mercer Hospital.

LETTERS TO A NEUROLOGIST.

To which are appended brief replies purporting to set forth concisely the nature of the ailments therein described with remarks on their appropriate treatment.

IX. From a Psychoneurotic Who is Hypochondriacal.

Rhode Island, April 16, 1908.

My dear Doctor:

Your suggestion, when I saw you at your office, that I should write a statement of my complaint, seemed quite reasonable until I began to try to put the facts on paper. Even then it seemed reasonable but also impossible. In the first place, I do not like to write, and in the second place I don't know what to put in and what to leave out. You have seen me and know that I am 21 years old, though I suppose I seem older because I have had to work since I was 14 years old and help to support my mother. This responsibility and the worry that I have had about myself have made me more mature than most young men of 21. I have a good position, and the respect of every one with whom I am associated, but if they knew me as I know myself, very likely I should forfeit them. I attribute all my troubles to masturbation, which I began when about 12 years old. After about three years I learned how injurious it was and stopped it. A few months later I began to have nocturnal emissions which were the result of my foolishness. About this time a great change came over me; I became regretful, remorseful, and self-conscious, and would often break out into a violent perspiration, particularly if I thought any one noticed me. All this was the result of the injury I had done myself. I tried to compensate for this injury by taking every kind of exercise that I was told would be beneficial, by taking cold baths, and paying great attention to what I ate, but none of them did me any good. I continued to have the same feeling and in addition a great deal of indigestion. When I was about 18 years old I was told that if I masticated my food thoroughly I would get rid of the indigestion. I began to do this, taking from an hour to an hour and a half to each meal.

Then it occurred to me that I could accomplish my purpose much better if I were to eat alone. At first I could stand it if persons were in the house, but if anyone were in the room my mouth would become so dry that I could not get the food soft enough to swallow and I would have a queer feeling of contraction in my stomach, and lose my sense of taste. My mother was then having a few lady boarders, mostly school teachers, which I persuaded her to give up because of my inability to take food if they were anywhere about.

Last February my mother went away to make a visit. She was to stay a week, so she cooked some food to do me during her absence. I got my own meals and ate them in my bedroom. During this time that no one was in the house I realized that it was unnecessary to chew my food until it became a liquid, my sense of taste returned, and I gained ten pounds in two weeks. My mother then came home, but I discovered at once that I could no longer eat while she was in the house. No matter if she was in another room I could not eat. I imagined she was listening, my mouth became dry, and this terrible constriction developed in my stomach, and it was impossible to go on

eating until she left. I persuaded her to put my meals on the table and then go out away from the house, to visit a neighbor, or to go to a store. Then I ate, but while doing so I was in constant fear that some one would come in. In order to avoid this I ate hurriedly with the result that lately I have had a great deal of indigestion. Now the neighbors are beginning to inquire why she always goes out at meal time, especially when it is raining and storming, and it is often embarrassing to give an explanation. But she must go or I starve, and I must keep up my strength. I always feel the sense of constriction of the stomach when I am in company, when I am talking, riding in the street car, etc., and especially if the person with whom I am in contact has shown more than ordinary interest in a personal or business way. I have it in the most troublesome way when I am with a girl that I know and like very well. It is hard for me to explain it in reference to this particular girl, but I must tell you that I have had lately a feeling that I would never let a woman get the better of me.

This has a queer relationship to what I consider to be the beginning of all my trouble. I have never had any inclination or desire to have certain relations with women; on the contrary, I have had a feeling of profound dislike for even the thought of it or for anything that suggests it. I do not think sexual intercourse is wrong or immoral but I do feel that if it were not for that I should not be in the condition in which I am now. Therefore I never go to a play or to a theater where they have ballet dancing, or where women play in short dresses, or where I would see anything which was likely to suggest these things to produce emission later when I am asleep.

A year ago, when the girl that I spoke about came to —— to visit, I met her and got to like her very much as a girl; I liked her just because it was she. I never thought of her in any other way than as a boy might think of an automobile. I used to go to see her often, but always after dark. She did not understand at first why I came then, but circumstances favored my calls at such time, and I was more ready to go because in the dark or with very dim light I do not break out into this awful perspiration, and I am not so terribly self-conscious and terrorized as I am at other times.

There are times when I feel perfectly well, even when I am with this girl. For instance I recall that some time ago I was calling upon her and I lay down upon a sofa; she came and sat beside me and caressed me. I felt as if a weight were lifted from me, and I said to myself, "I am perfectly well." If I should plan to repeat this I would get into such a state of excitement and distress, that I think I would go mad. In the first place I have to distinguish this girl from her sex. I am not at all sure that I make clear to you what I mean, but I have the conviction that the sex, meaning women, have had something to do with getting me into this awful condition. If they did not exist, that is, if there had not been something in me which demanded or called for their existence, then I should not be in the condition in which I am. My reasons, then, for not wanting to have anything to do with them is that I want to put this whole question of sex entirely outside my thought, and this is what I mean when I say that I have the feeling that I shall never let a woman get the better of me. But with this particular girl it seems that I don't feel that way and especially when I am with her. When I am not with her she is in the category of her sex, and the thought of her fills me, sometimes, with these extraordinary feelings which are a mixture of fright, anxiety, terror, and despair. I feel sometimes I can't withstand the sensation another minute, and if I don't get relief I'll explode, or go up in the air, or in some other manner cease to be.

I have explained to her a great many of my troubles, but of course she does not know what they come from. Once when she came out to —— I met her at the train and I told her I had to go to ——. She wanted to go with me. I thought I could not stand it, as it would be very light in the train, but finally she persuaded me to take her. The perspiration simply rolled from me all the way and I was most uncomfortable. I kept saying to myself, "If ever I get out of this I'll never get into such a mess again." Had it been dark I should have enjoyed myself. When we returned I went home, changed all my underclothes, which were so wet they dripped when wrung, and then went to her house. The light was low there and I felt all right. To-morrow she is coming up to —— to see a ball game. I am going to play. I shall suffer more than you can imagine because I know she is there. I wish she were not coming. I will have a nervous sensation for fear she will see something in my face that will make her not care for me and I shall avoid her in every possible way. Unless she approaches me it is very probable that I shall go home without speaking to her. She knows I care for her although I have not told her in so many words.

Last summer she wanted to give me a ring. I said, "No, I am not worthy of it." I felt unworthy because I had masturbated and injured myself by so doing. In the winter, however, when she asked me again to take it, and keep it as long as I loved her, I thought "I can do that conscientiously," but I did not say in so many words, "I love you." She is a brilliant girl in company, a wonderful girl, and she is very fond of me.

She has written between forty and fifty letters to me, but I have only written one to her. I cannot bring myself to write because I feel that some time the written letter might be used to my disadvantage. Sometimes, you see, I am so nervous that I can scarcely sign my name.

If I did not have so much worry about eating, that is if I could give time to anything else, I might get well, but I have fallen away terribly, particularly around my chest, although I am pretty good weight, that is I weigh 145 pounds and I am only 5 feet 5 inches high, but I am sure that my body has fallen away a great deal. It is always harder for me to eat dinner than any other meal, and particularly if I have seen a great many people all day or have been excited in any way.

I have had to give up going to church and to entertainments. Occasionally I go alone to the theater, but always I have to have an aisle seat, so that if the impulse to get up and go out comes over me I can do so. Once or twice I have been to the theater and had a seat two or three from the aisle but I perspired so all the time and was so painfully self-conscious that I did not have a moment's enjoyment. As a rule when I am in the theater or a similar place, I am able to forget myself only when the lights are turned low. Then of course I can't go anywhere for amusement like other persons. I can't go into a restaurant, I can't go on excursions, I can't go to parties, for the entertainment of all of these is mixed up with eating and with women.

I like crowds; for instance, there are few things I like better than going to a baseball game; then, with a great many people around me, no one observing me, I am without a trace of nervousness. I can talk to anyone at such times, who speaks to me casually and does not take very much interest in me, just as any normal person can.

I am convinced that I brought this all upon myself, and I know I did myself harm. If I don't get out of it I don't know what is going to happen to me. As I have told you, I am falling away around my chest, as anyone can see who will look at it, and I am sure that one can't go on living the way I do.

Another thing that troubles me is that I don't know what to do about this girl. She seems to me to be the finest thing in the world, but I am not able to conduct myself toward her as a man should. Please help me.

Yours faithfully,

New York, April 23, 1908.

Dear Sir:

The letter which you wrote to me on April 16 I have received. Despite what you say in the beginning of your letter about your inability to write, it seems to me that you have succeeded in this instance in letting me know something of yourself.

Your case is of the greater interest because it seems, even from the brief recitation that you have made of it, that your obsessions and your delusions are founded upon a sexual basis. A well known Austrian writer, Freud, to whom we are indebted for helping us to interpret such disorders as yours, has suggested that most cases of this kind are founded upon such basis.

I do not believe that the cause which you attribute for your ills, namely onanism, is the fundamental one. In fact, I am not at all convinced that it has had anything to do with your present complaint. In the first place, you must know that the majority of boys at some time in their lives do what you did, and which you are now making such a fuss about. And you must likewise know that no injury flows from it, otherwise the world would be filled with human wrecks. Why should you, a vigorous, robust, young boy, who was addicted to it a very brief time, be wrecked and the countless others go entirely free?

I have no doubt that your disorder is upon a sexual basis but it will require a careful investigation by the so-called psychoanalytic method to determine just what feature of sex disturbance is responsible for it.

It will not cure you to be told that the unnatural sexual indulgence of your boyhood is inadequate to have caused your present condition. It will not suffice you to be assured that if you will exert your will power you will overcome your most distressing symptoms. It will not avail even to convince you by logical argumentation that you must be well nourished to weigh 145 pounds when you are but 65 inches tall, and that therefore the belief that you are falling away is a delusion. In fact argument, persuasion, exhortation, assurance, contempt even (that weapon which pierces the shell of the tortoise) are of little utility in such cases until after the patient has been assisted to a psychic state similar to that which existed when the symptoms first manifested themselves. You ask how this is to be accomplished? And I say to you, I profess to do such things, and I shall be glad to try to do it with you.

Such treatment is called psychotherapy. It is a big word, and now that the public, and here and there an enthusiastic cleric have got hold of it, it is likely to have the vogue that appendicitis had a decade or so ago. It is not at all new in the art of medicine. In fact it antedates Esculapius, and a very fair brand of it was in use at the time of the Pharaohs. However, there came a time when it fell into desuetude in Boston, and so it had to be revived. The renaissance was attended with slight raising of the voice on the part of its sponsors. This is the equivalent of a lyric outburst or of a dramatic apostrophe, or even of an impassioned arraignment, in less cultured centers. Naturally advance has been made in the understanding and application of it during these past few years that have revolutionized every art save that of the poet and artist.

You may do a great deal to assist the physician who essays to cure you. You may assume, for instance, that you are in error about the cause of your symptoms. You need not furnish a cause just at present. Assume that you do not know and leave it to others whose lives are devoted to ferreting out the cause of disease to find out. You may read books whose purpose is the instruction of persons such as you in the nature of their symptoms and diseases. For this purpose I recommend a small book recently published by Lippincott, of Philadelphia, entitled "Why Worry?" from the pen of a physician in a neighboring city long known as the Athens of America, sometimes reviled as the cradle and nursery of "Antis" of every description, but universally recognized as the abiding place of the Ancient and Honorable Artillery. Its author, Dr. George L. Walton, has succeeded in putting the facts about psychoneurotics, of which you are one—if you will forgive me for calling you names—so clearly and so intelligibly that any one can grasp and understand them. More than this, he writes with such insight and sympathy, such candor and simplicity, that the reader cannot fail to appreciate that what is said is founded upon experience, knowledge, and wisdom. You will find in it, I have no doubt, much that will aid me in getting you well.

Finally, don't neglect the poets. They are a great adjuvant to medicine. You will not accuse me of disrespect for the cloth or irreverence for that which it represents symbolically when I say that if I had to choose between Emerson and the Emmanuel Church as an aid to the practice of medicine, I shouldn't hesitate a moment. I don't decry prayer while exalting poetry, for I believe with the Epistler James that the effectual fervent prayer of a righteous man availeth much. While I am speaking of poetry I suggest that you commit to memory the following stanza from Cowper and whenever you get wrestling with the idea that your troubles have flown out of youthful folly counteract it with "Truth," which says:

> "Past indiscretion is a venial crime,
> And if the youth, unmellowed yet by time,
> Bore on his branch luxuriant then and rude,
> Fruits of a blighted size, austere and crude,
> Maturer years shall happier stores produce,
> And meliorate the well-concocted juice."

Finally I want to say to you that I am sure that you will recover, and that you and she, "the brilliant girl, the wonderful girl," will live happy together forever afterward.

Yours, very sincerely,

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

SUBSCRIBERS TO CHARITIES—DR. HALL-EDWARDS—LIVINGSTONE COLLEGE—MEMORIAL TO DR. FANDON—ST. MARY'S HOSPITAL—THE BISHOP'S ADDRESS—ROYAL SOCIETY—RESEARCH DEFENSE DISCUSSION—RATS—SIR H. PITMAN.

LONDON, July 3, 1908.

On Friday afternoon, at an influential meeting at the Mansion House, it was resolved to establish an "Association of Subscribers to Charities." The objects of the new organization, as stated by Lord Rothschild in proposing the resolution, are to promote systematized cooperation between and coordination of the charities of London, with a view to the establishment of uniform principles in the administration of relief of distress in the metropolis; to promote systematic interchange of information between metropolitan charities in order to prevent overlapping and the waste of resources, and to strengthen the financial position of those charities which carry out the objects of the association. Lord Rothschild said their object was not to interfere with such funds as the King's Hospital Fund or to induce the Mansion House to depart from its traditional policy of inviting subscriptions for good works. But it was obvious that there must be overlapping in the administration of the Poor Law and the spending of money for charitable purposes. The figures supplied were almost staggering—ten millions in charities and five in Poor Law.

Lord Avebury explained some of the steps which had led to the meeting and Lord Lichfield urged the necessity of preventing overlapping. They had worked together to this end and now came forward with a comprehensive scheme. Their relations to the Charity Organization Society and to the King's Fund were entirely satisfactory. They would not be a destructive force in regard to charities, but would strengthen them and increase their efficiency.

Of course, it is chiefly as it may affect hospitals that this movement is interesting to medical men. It is well known that the Charity Organization has at times interfered in a manner that has caused offense, and its recommendations and criticisms have sometimes provoked intense opposition. But hospitals are a sort of specialty among charities, and their management always requires the assistance of medical men—a point some administrators have too often ignored. It is not, however, to be denied that there is room for pressure from without in the case of some of the competing charities as much as in that of other rival charities. Such pressure has been exercised in the past by the King's and the Sunday Funds, though by the latter not always so wisely as it might have been. The new society will, therefore, need much circumspection.

There are 17,000 or 18,000 charitable institutions of different sorts in London, and the proposal to effect a reversal of their destructive methods of isolation and separation of interests, with a view to strengthening the well-managed is one calling for clear thought. Well may the association announce that it will not concern itself with debatable social problems or questions of State aid. But enough will remain to absorb the energies of an active body. Let us hope that those who are responsible for establishing the new body will not be content to become ornamental advocates of imperfectly digested schemes or the mouthpiece of an official. Lord Lichfield estimated the cost of organization at £1,500 a year. If that is to be spent in an office, a secretary and clerk, can we anticipate much result, unless the committee or council, as they may call themselves, are ardent workers in the cause.

A minimum subscription of £1 1s. is to constitute membership, and this is to secure the representation by the association in any negotiations which the member may enter into with a charity to which he subscribes. This almost suggests leaving the work to those who are at present doing it—each in his own way.

On Sunday afternoon Dr. Hall-Edwards underwent a second operation, his right hand, except the thumb, being amputated. You will remember that in February the left forearm was removed on account of the injuries caused by his work with the Röntgen rays. In spite of the great suffering he has endured during about six years, sleep being only obtained by drugs, he has kept at work. I am told he has kept a careful record of his case and hopes to complete a work on *x*-ray therapeutics which is now far advanced. In that he will, of course, point out the errors in his pioneer efforts, and in which he hopes others may utilize the rays without danger.

Livingstone College, named after the great medical missionary and explorer, celebrated its commemoration day on Monday. The object of the institution is to give an elementary medical training to persons about to engage in missionary work. Dr. C. F. Harford, the principal, said more than 300 students had passed through the college. They are of all denominations. The primary object of the training is to safeguard the health and lives of themselves and their brethren, but they do not pretend to be medical missionaries. They could not do the work of such. Nevertheless, they learn things of immense value to them in strange lands and far from medical aid.

Sir P. Manson delivered an address on the "Importance of a Knowledge of Tropical Medicine by Missionaries, Especially in View of Recent Discoveries." He described the advance of our knowledge in many of these diseases and urged the unfairness of sending men to face avoidable risks. Martyrdom was one thing, suicide another, murder still another. To send a missionary to the tropics without the information needed for saving his life was an act he did not care to characterize. Bishop Molony, a former student of the college, and Bishop Tugwell also addressed the meeting.

An interesting ceremony took place at the Middlesex Hospital on Monday. Dr. Cayley (senior physician) unveiled a bronze medallion in the main corridor of the building in memory of Mr. F. A. Fandon, who was for twenty-eight years resident medical officer. The committee which collected the subscriptions for this memorial also presented to the board medals of gold, silver and bronze, with a portrait of Mr. Fandon, on the obverse, to be awarded yearly to three nurses. The memorial bears the words: "An able administrator, a faithful servant of the hospital, a much-loved friend."

At St. Mary's Hospital the Bishop of London distributed the prizes and told the students his work was connected with theirs, though perhaps his cooperation was not wanted. That, however, did not discourage him. He was often fighting against so-called Christian Scientists, who were excellent but misguided people. They did not appreciate the sacred character of the healing art as carried on by ordinary medical practitioners. He looked on it as God's plan that men should discover His secrets by their brains, and revelations so obtained came from God as much as the Bible. Truth could not contradict itself. He apologized to the doctors for having been ill only once in nineteen years—but then he felt that the doctor came from God as much as a parish priest. There was another link between his hearers and himself in the fact that both served the poor. It ought to be known to the generous public that some of the areas served by St. Mary's Hospital were among the poorest in London and £50,000 would be very welcome to the institution.

The Royal Society gave its second conversazione on Monday, when as many scientific exhibits and curios were shown as usual to a brilliant company. The Egyptian Survey Department attracted great attention. There were plans of predynastic burial places and photographs of crania showing various racial types at different periods. These discoveries were examined by anatomists on the spot. There was a gouty foot, said to be of the sixth century, and a number of feet and hands of which the bones had been interchanged, pointing to carelessness by the embalmers. Stereoscopic radiographs of molluscal shells were exhibited by Dr. Rodman to show that by *x*-rays they can be examined as to both horizontal and vertical appearances without destroying or damaging the specimen.

At a meeting said to have been arranged by the Research Defense Society, Professor Starling read a paper on "The Use of Animals in Experiment." He argued that man's attitude towards animals consisted in allowing them to exist or encouraging their existence in direct proportion as, by their activity or by their bodies, they aided him in the struggle for life. It was therefore difficult to object to their use for acquiring knowledge directly related to the preservation of mankind against disease and death. Cures for diphtheria and other diseases were discovered by experimentation. Pain did not exist in the laboratories of this country. Even discomfort occurred in only an insignificant minority of experiments.

Miss Hageby then spoke for the antis, declaring that ethics forbad torture and that she was not con-

vinced that vivisectors were not merely callous but were guilty of gross cruelty. That is the sort of argument one expects from the female antis. Dr. Hadwen afterwards denounced in an excited manner the moral basis of Prof. Starling's statement. He asked what right had man to inflict pain in order to escape it himself? Then he declared that all the surgical and medical knowledge we have is due to clinical observation and nothing else! This Dr. Hadwen is apt to indulge in positive assertions—some of which provoke incredulity. The other day he said he had verified 100 cases of burial alive and nearly 300 in which persons had narrowly escaped the same fate! "Prodigious!" as Dominie Sampson would have said.

If the hysterical antis are sincere and consistent in their horror of the sufferings of animals, they have lamentations in store for the fate of rats. The Society for Destroying Vermin is about to organize throughout these islands clubs for killing rats and to present prizes for the biggest bags. The society holds that the end justifies the means and cares not what method of slaughter may be adopted. The connection of rats with disease is sufficiently established, but the society is further impressed with the economic loss due to their depredations. It has been estimated that there are as many rats as human beings in the British Isles and each costs about seven shillings and six pence a year. On the island of Degat, off Denmark, a pair of young rats escaped from a cage three years ago and last year the Danish Government announced that the island was swarming with rats, but bird life was ended. The fight of humanity against rats is not a new one. The Romans struck medals to record victories over the vermin. Some of these medals have lately been found by Dr. Sambon. Denmark has voted £5,000 a year towards rat destruction, and other countries are active.

It is intended by the society above named to organize an exhibition in London to represent the plans that have been tried within historical times to meet the danger from vermin. Within the next few weeks the matter will be discussed at the Royal Society of Medicine.

Sir Henry Pitman, many years Registrar of the Royal College of Physicians, attained his 100th birthday on Wednesday, July 1. Numerous congratulatory messages reached him—among the first one from the King. Sir Henry spent the day quietly with his family. His health is good, but his eyesight is failing. Lady Pitman, considerably younger, is also in good health. They were married in 1852. Sir Henry was many years physician to St. George's Hospital and was knighted in 1883. He recollects the rejoicings in Hyde Park after the battle of Waterloo and has many other interesting reminiscences.

HEXAMETHYLENAMINE AS A SPECIFIC IN TYPHOID FEVER.

To the Editor of the Medical Record:

Sir:—Recent publications have shown that medical science is now in possession of a drug which will greatly aid the human system in its struggle against the *B. typhosus*. This drug, hexamethylenamine, U. S. Ph., was first used as a urinary antiseptic, and later was shown to be of the greatest value in urinary infections when the infecting organism was the typhoid bacillus. Because of this fact it has come into almost general use in urinary infections arising during or after typhoid fever, and following the suggestion of Richardson it is administered by many as a prophylactic against these infections. Richardson recommended its use in the latter half of the disease, and in one hospital with whose work I am familiar it was the custom to administer this drug on two days of the week during the whole course of the disease.

Some recent work done by Crowe (Johns Hopkins Hospital Bulletin, 1908, XIX., 109) has greatly extended the field of usefulness of this drug, and has, I believe, made it imperative to give hexamethylenamine in every case of typhoid fever from the beginning to its termination. By his experiments Crowe demonstrated that after administration by mouth hexamethylenamine, or its decomposition product, formaldehyde, was excreted in the bile, and excreted in an amount sufficient to sterilize completely a gall-bladder infected with the typhoid bacillus and other organisms. He has also shown that it is excreted both through the liver and through the gall-bladder. The far-reaching value of this discovery is apparent when we remember the frequency of gall-bladder infections caused by the typhoid bacillus and that the gall-bladder is probably an abiding place for this organism in every case of typhoid fever. He has further proved its excretion by the pancreas, and has demonstrated it in the cerebrospinal fluid, synovial fluid, saliva, pleural effusion, and blood.

We have here, then, a drug which is directly antagonistic to the typhoid bacillus and which, after administration by mouth, permeates every part of the body and is known to be excreted in several of the favored haunts of this organism—the meninges, the bile passages, and the kidneys. If the body could tolerate a sufficient dose, every typhoid bacillus within it might be rendered inactive by hexamethylenamine and typhoid fever aborted. In some, perhaps many, cases it may be able to do this. However, it has been definitely proven that this drug will destroy at least some of the typhoid bacilli present in the body, and if the invading force is diminished only one-eighth the tide may be turned in favor of many and their lives saved, and much suffering and death from complications and sequelæ may be prevented. As to the dosage, Crowe has shown that when 75 grains a day are given the amount in the bile is sufficient for a pronounced bactericidal action, and it should, I believe, be given almost to toleration, a careful watch being kept of the urinary system. My experience is as yet too limited for presentation, and the above is put forth merely as a suggestion.

Heberden Beale, M.D.

Fort Worth, Tex.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 9, 1908.

Obscure Fever in Infancy and Early Childhood.—J. L. Morse says that a daily rise of temperature above 99.5° F. at the age referred to is abnormal, and is a manifestation of some diseased state. Among the conditions which give rise to it he includes endocarditis, typhoid fever and malaria, starvation in the new-born, dentition, toxic absorption from tonsils and adenoids, otitis media (a most common cause), cervical and bronchial adenitis, anemia, rachitis, syphilis, intestinal toxemia, etc. Finally, he says that there is a class of cases of continued fever in infancy and early childhood in which the most careful examination fails to find any cause for the fever, in which no modification of the diet is of any avail, and in which the general condition is unaffected by the child being apparently well and gaining normally in weight. The temperature may remain normal for many weeks, or even months, in such cases, and finally cease, without any cause for it ever being discovered. In these cases the most reasonable explanation is, in the author's view, some obscure disturbance in the bodily metabolism. The history of such a case is thus portrayed: A girl of two years had a slight cold, lasting about a week. The temperature, which was first taken during the cold, did not drop when the child recovered, but continued elevated. To make a long story short, it ranged between 100° F. and 101° F. in the morning and 102° F. and 104° F. in the afternoon for eleven months, finally coming slowly down to normal and remaining there. During this time she appeared perfectly well in every way and gained steadily in weight and height. Repeated physical examinations failed to show anything abnormal. The urine was always normal, and the blood never showed any parasites or abnormalities in the number of red or white corpuscles. She is now, four years later, an exceptionally large, strong and healthy girl. Such cases justify the conclusion that if a careful study and thorough examination of the child does not reveal the cause of the fever, there is, in the vast majority of cases, nothing serious the matter, and no cause for anxiety.

New York Medical Journal, July 11, 1908.

The Treatment of Erysipelas.—D. B. Allen extols the use of carbolic acid in this disease, but claims that the strength of the applications commonly advised is far too weak to obtain satisfactory results. Proceeding on the theory that the affection is an infection of the subcutaneous tissue and lymphatics by the streptococci, he advises the painting of the area involved with the pure acid, extending the operation three-eighths of an inch beyond the line of demarcation. This is allowed to remain until it becomes white, when it is washed off with 95 per cent. alcohol. The penetrating action of the carbolic is a direct germicide to the streptococci already present, and the ring around the area serves as a strong barrier beyond which it is almost impossible for the infection to spread. This line of treatment causes an intense smart-

ing and burning which lasts but a few moments and is quickly relieved by alcohol. In some cases the burning continues for an hour or two in which a cloth saturated with alcohol is laid on the area. In case of extension into the eyelids where it is impossible to use the pure carbolic, a two per cent. carbolic acid solution in unguentum hydrargyri ammoniatum to be applied frequently is ordered. The results in a series of 12 cases thus treated have been more satisfactory. The skin heals without scarring.

The Significance of a Blood Analysis in Appendicitis.—C. C. Sichel asks, "Can we depend upon the leucocyte and distinctive polynuclear counts as a positive indication for or against operating?" He replies, "with the first leucocytosis and increase of the distinctive polynuclear percentage, operate." Histories of three cases of a series are given. All cases showing a leucocytosis and a polynuclear increase were operated on, without finding a single case in which there was a purely catarrhal condition. All interval cases or those not showing a leucocytosis, etc., which were operated on showed that no acute process was in progress. The author strongly advocates operation as indicated by blood findings in all cases of appendicitis. When leucocytosis and polynuclear increase are present, operate at once. When there is no increase in the counts watch the blood picture in repeated examinations and be guided by the findings plus the patient's general symptoms.

The Management of Chronic Endocarditis During the Stage of Compensation.—S. A. Stein emphasizes the necessity of individualizing all these cases, noting that every patient reacts differently to drugs, dosage, to different preparations of the same drug, and to different forms of mechanical stimulation. All compensation is, of course, relative. Alcohol should be dispensed with if possible, as also tobacco, tea and coffee. Superfluous adipose tissue should be gotten rid of, but great care is called for as to diet, exercise, and drugs. Hygienic care is as necessary as in tuberculosis. All emunctories must be kept as nearly normal as possible. Rest in the recumbent position and sleep are all important. In cases with insomnia, hydrotherapy is of great value as a hypnotic and cardiovascular regulator. If drugs are used, sodium and ammonium bromide are less depressing than the potassium salt, while the trional-veronal group are of great service. As nearly all cardiac stimulants act as vasoconstrictors, it is well to combine with them the iodides and nitrites. Codeia is without doubt the safest of the opium preparations when we wish to combine a stimulant and sedative. The method of choice from among all three plans must be influenced by the age, physical condition, and social status of the patient. At both extremes of age, naturally, the severer forms of exercise are excluded. Before the age of puberty there is nearly always present a strong tendency to rapid hypertrophy, and frequently as rapid a degeneration of the hypertrophied muscle, making the prognosis bad in most of these cases, so that the physical activity and restlessness should be curbed rather than added to. At the other extreme, overexertion, being less likely to occur, and activities being naturally lessened, once compensation is established, the natural hygiene of old age will be that of the accompanying endocarditis, which is, as a matter of experience, very well borne.

Journal of the American Medical Association, July 11, 1908.

Muscular Coordination by the Nervous System.—C. E. Beevor analyzes the muscular mechanism of movements, understanding by this term the single movement of one joint, and not the combination of movements as in walking. He classes the muscles, first, into the prime movers, which come into action in a definite order according to the amount of work to be performed. The will does not appear to have any power to alter this order (except, perhaps, by trained exercises); second, we have the synergic muscles, which come into play when the prime movers have an additional action that is not wanted in the particular movement to be executed. For example, the biceps is the chief supinator, but it is also a powerful flexor, and when supination without flexion is done the triceps contracts as a synergic muscle and counteracts the flexion of the elbow by the biceps. The relations between the prime movers and the synergics are very close, and apparently the brain has no power to moderate the impulse sent to the latter to make them act proportionately to the weak prime movers in case of their paresis or paralysis, hence we have in such cases movements other than those desired. Lastly, we have the fixation muscles fixing the joint when such fixation is made necessary by pressure or displacement. A certain amount of stress on the joint is required to call these into action. The antagonists to the prime mover muscles are relaxed under normal conditions, except in case of some unopposed movements which are required to be suddenly stopped, but in certain cases of functional paralysis this inhibition of the antagonists may fail, and Beevor considers their contraction as a symptom of functional as opposed to organic disease. It also occurs, however, in tetanus and from the toxic action of strychnin, which, according to Sherrington, "change the reciprocal inhibitions, normally assured by the central nervous mechanism, into excitations." Beevor considers all the physiologic evidence to be in favor of the location of the linkage of the ultimate co-ordination of movements being in the spinal cord, and that most probably this nervous mechanism is situated in the cells of the posterior cornua, where, as shown by von Monakow and Schafer, the pyramidal fibers end, instead of the anterior horns, as was formerly supposed. Whether this mechanism is the same as that used for reflex movements, he considers uncertain.

Psychiatric Prognosis.—F. X. Dercum discusses the prognosis of insanity. He recognizes the following elements in the problem: First, the clinical type; second, the presence or absence of actual quantitative mental loss; third, the systematization of delusions; fourth, the fixation of symptoms; fifth, age; sixth, sex; seventh, the presence of morphologic or somatic stigmata; eighth, the significance of heredity; ninth, the bearing of social status. He takes up these points *seriatim* in the forms commonly grouped under the name of dementia præcox, a designation which, he points out, is misleading, since confusion and not dementia dominates the clinical picture. The points on which he lays special stress as influencing the prognosis in mental disorders are: First, the presence or absence of actual dementia; second, the presence of systematization of delusions; third, the presence of fixation, and, fourth, the social status of the patient as favoring the necessary measures and conditions favoring recovery. Heredity is, of course, important, but it influences the prognosis of a given attack only in a general way; it cannot, Dercum says, give a definite clue as to either outcome or duration. Other factors of the prognosis are the bodily condition and the significance of visceral complications. In a general way, we may say that marked physical without mental improvement, and the converse, the less frequent condition in which there is mental without physical improvement, are both to be regarded as unfavorable. The marked persistence also of hypochondriacal ideas, especially those of psychic or somatic negation, are not infrequently found associated with chronic and unrecoverable conditions. Special factors, such as interruption and cessation of progress, also influence prognosis unfavorably, and an incomplete recovery renders recurrence more probable. Among favorable features may be mentioned regularity, of course, concomitant physical and mental improvement, and the realization by the patient that he has been ill. It is, of course, to be understood that attacks due to extraneous causes, as in toxic and exhaustional cases, have generally a better prognosis than those that are essentially neuropathic, and that marked degenerative stigmata may have a certain significance.

Antigonococcic Serum.—A. A. Uhle and W. H. Mackinney report results of the use of antigonococcic serum in twenty-three cases of the various types of gonorrheal infection. They find that, so far as their observations indicate, the serum has little if any curative action on the urethral condition, the improvement observed in some patients being more attributable to rest and hygienic treatment than to any specific action of the serum. None of the patients with gonorrheal prostatitis was cured; of seven with epididymitis, improvement was observed in three, but the authors are inclined to credit this as much to other measures employed, rest in bed and elevation of the scrotum, as to the serum. "If conclusions," they say, "can be drawn from this limited number of cases, it appears that neither the number of injections nor the time elapsing between injections has any influence on the results of the treatment, as in no case was there what might be termed a prompt improvement, which is to be expected from an antitoxin treatment." Possibly, they suggest, better results might have been obtained with larger doses than the 2 cc. employed. The best results were obtained in gonorrheal arthritis. Three patients were promptly relieved and all local evidences of inflammation had subsided in less than two weeks. In one of these Bier's treatment was also used. Considering the usual obstinacy of this condition, the results are encouraging; with no other treatment except opsonotherapy and Bier's method have such good results been obtained. One patient with gonorrheal myositis showed little improvement from the serum, but responded promptly when the Bier treatment was used in addition. A general urticarial eruption following the use of the serum was observed in seven patients. Besides

this and the itching it caused, and a slight pain at the site of the injection, no general or local toxic symptoms were observed.

The Eye in Multiple Sclerosis.—W. A. Holden publishes reports of cases illustrating the ophthalmoscopic and visual changes occurring in multiple sclerosis. The pathologic changes seem to affect mainly the medullary sheaths, the axis cylinders and ganglion cells remaining long intact. The visual disturbances fall chiefly into three groups: (1) Concentric contraction of the field of vision; (2) central scotoma with normal peripheral limits of the field, and (3) a combination of central scotoma and concentric contraction of the field. There may be variations of these types and the visual disorders are apt to precede the other symptoms, sometimes for years, are often of sudden onset, and if excessive, usually improve. Thus all the changes differ radically from the slow, progressive atrophy of tabes. The ophthalmoscopic appearances are, therefore, of value in the early diagnosis, especially in excluding hysteria and early paresis. Holden reports one case which he is inclined to consider multiple sclerosis from the eye symptoms alone, corroborating symptoms having as yet failed to appear, and he expresses an opinion that "a non-toxic retrobulbar neuritis, if not due to a sinusitis or directly to syphilis, diabetes, a neoplasm or trauma, is, as a rule, a manifestation of multiple sclerosis, although no other symptoms of the disease may be present." More than half the patients with multiple sclerosis who complain of failing sight have a central scotoma and the diagnosis is retrobulbar neuritis.

The Lancet, July 4, 1908.

Latent Dysentery in Central Africa.—H. S. Stannus refers to the case of a man of thirty years, admitted to hospital after a fortnight of fever, headache, malaise and loose bowels. He had taken quinine and Dover's powders with a diet of goats' milk. There were no nausea, vomiting, or cough. He had had two or three pasty stools, but without mucus or blood. He had previously had malaria. Two ring-form parasites were seen in the blood specimens. Urine was normal. He was placed on quinine, but no effect was produced on the fever. He continued to have two daily stools, watery, with little fecal matter, but neither mucus nor blood except on the second day after admission, when what appeared to be a small old blood clot was passed. No improvement was effected by twenty-grain doses of bismuth three times a day for three days. Microscopical examination of the stools proved negative as regards amœbæ. The tongue was thickly furred and the patient complained of weakness, headache, and profuse sweats in the evening. The spleen could just be felt; the liver showed no enlargement to percussion or tenderness to palpation; there were no other physical signs in the chest or abdomen. At the end of the week, during which time no other malarial parasites had been found, quinine was discontinued and it was determined to try ipecacuanha. It was given in wafer, in twenty-grain doses, on two consecutive days on an empty stomach, twenty minutes after a twenty-minim dose of tincture of opium, as recommended by Manson. The result was immediate: the temperature commenced to fall, reaching normal in four days, and thereafter not rising again; the stools became more and more formed, being normal in three days; the tongue cleaned, and the patient expressed himself as feeling much better. The convalescence was uneventful, full diet being attained by the end of a week of normal temperature.

Endemic Funiculitis.—Under this title A. Castellani describes a peculiar form of acute suppurative inflammation of the spermatic cord occurring in Ceylon. He has examined the pus in five cases and in all located a diplostreptococcus, the culture reactions of which he describes, as also the symptomatology of an attack. The condition on examination might be easily mistaken, he says, for a strangulated hernia. As a rule the disease has no tendency to spontaneous recovery. The only effective treatment is orchiotomy, cutting the inflamed cord as high up as possible. Unless this is done general sepsis sets in. The author's conclusions are thus expressed: (1) There is endemic in Ceylon, and probably in other parts of the tropics, a peculiar affection of the cord which it seems to me has sufficiently characteristic symptoms to be ranked as a separate disease. This affection might be named "endemic funiculitis." (2) A diplostreptococcus is constantly found in the pus. Further investigation is needed to decide whether this diplostreptococcus is the primary cause of the disease or, as the author is inclined to believe, is merely a secondary agent playing a rôle only in the suppurative stage of the malady.

Some Rare but Important Surgical Injuries Brought on by Violent Exercise.—P. Haglund refers to a series of cases in which diagnosis was obscure until the introduction of the *x*-ray. The most common lesion is one of the tuberosities of the tibial or "Schlatter's Disease." It is frequently seen among athletic boys who have presented a tender spot just where ligamentum patellæ is attached to the tibial tuberosity, a condition which, although it does not ordinarily necessitate absolute rest in bed, yet is capable of causing much inconvenience and pain and of preventing the sufferer from taking part in games of any kind. Every movement which puts a strain on the ligamentum patellæ gives rise to acute pain. Something has affected the attachment of the ligamentum patellæ to the tibial tuberosity. It is often impossible for the patient to tell just when he began to have trouble. Sometimes it is referable to a sudden athletic exertion, but symptoms are not necessarily so severe as to prevent the patient from continuing his exercises for some time. That the injury is productive of so little discomfort at the time depends no doubt upon the fact that the fracture of the trunk-like projection takes place without involving the perichondrium which covers it. And as cartilage just as little as bone is provided with nerves of sensation, it is easy to understand how such a lesion can occur without any pain at all. Meanwhile a serious weakness has been caused at the point of insertion of the ligamentum patellæ and each contraction of the extensors of the knee aggravates the condition. In this way an irritation is constantly operating which leads to an increase of the inflammatory symptoms. The patient becomes more and more an invalid. The lesion is, though not serious, very troublesome. It usually lasts six months, but two years may elapse before the patient gets a useful limb again. Much depends on the amount of anatomical disturbance and on how far the patient is careful not to irritate the injured cartilage. A similar lesion may also occur at the epiphyseal center of ossification of the calcaneum, just at the attachment of the tendo Achillis. There may be a separation or fracture of this center from some great strain involving the calf muscles. A third injury of this nature takes place at the tip or tubercle of the os naviculare of the foot. It sometimes happens that the ossifying center becomes fractured without any injury to the perichondrium and, therefore, without giving rise to any pain. The injury is caused by severe strain to the instep involving violent stretching of ligaments which spring from this point. Games, *e.g.*, lawn-tennis and football, are responsible for the lesion, as is also strenuous dancing. This explains why girls exhibit this particular injury more often than the two preceding ones. The condition may be compared with certain troubles caused by the presence of what has received the name of "os tibiale externum," a small adventitious bone occasionally met with at the tip of the os naviculare pedis. It may be questioned whether these ossa tibialia externa do not derive their origin from fractures of the scaphoid tubercle in early life.

Thoracostomy in Heart Disease.—A. Morison refers to a previous communication from himself in which he suggested the severing of pericardial adhesions for the relief of cor bovinum, but adds that more recently the conviction has been growing in his mind that it is less the tethering of the heart than its bulk and force of systole which are the determining factors in the situation, and what was desired was an operation to afford adequate room for the free action of the enlarged organ. Brauer of Heidelberg had already suggested that the adhesions in adhesive pericarditis should best be left alone and the incarcerated heart freed from its bony encasement. From all these considerations has come the term "thoracostomy," and reports are given of several cases operated on. In the present paper the author adds records of another case successfully treated by operation and six months' hospital residence. A shield was worn over the chest, corresponding to the area from which the ribs had been removed. The perpendicular measurement of the gap was seven centimeters. Exploratory puncture should be made through the fifth rib cartilage. If the intrapleural area is free, we are able to settle in a few minutes the diagnosis of adherent pericardium, and on that ground alone the operation is considered justifiable. If we are unable to feel the intrapleural spaces we know that there are adhesions. The presence of such costopericardial adhesions, with which in the case of enlarged heart it may be assumed that visceropericardial adhesions are associated, may indicate the removal of a portion of the sternum in addition to the ribs, as practised by Simon in two of Brauer's cases. But if the clinical phenomena can exclude such adhesion, which, it will be admitted, is often a difficult matter, and, especially in aortic cases, in which the character and direction of hypertrophy usually displace the volume of the left ventricle downwards and to the left, it will probably be found that

the best guide in most cases to the amount of thoracostomy necessary will be the area of forcible cardiac impulse, and that the removal of ribs and cartilages without interference with the sternum will fulfill every purpose. It may be unwise to give the heart too much room to act in; it is certainly quite possible to give it too little.

British Medical Journal, July 4, 1908.

Surgical Emphysema.—A. S. Woodwork was called to see a man who, in stepping from an omnibus before it had stopped, fell upon his face, giving his neck a severe jerk, and causing his nose to bleed. He walked home, and an hour and a half later, the epistaxis having ceased, partook of dinner, consisting of cutlets, vegetables, etc., and a glass of soda water. His wife then noticed that his face and neck were beginning to swell, and he also felt that his collar was tight. An examination showed extensive surgical emphysema, surrounding his neck and reaching from his eyes to the fourth rib on each side. There were two or three superficial abrasions upon the nose. No facial bones or ribs were broken, and he complained only of a slight stiffness of the neck. At the back of his palate was a clot of blood, and the removal of this disclosed a black object sticking into his nasopharynx just above the pillars of the fauces of the right side. This was detached with some difficulty, and proved to be the vulcanite mouthpiece of his pipe, measuring 2¼ inches in length. Until then the author had heard no mention of a pipe, but the patient now produced the bowl, to which the mouthpiece, with the exception of a minute portion, fitted exactly. He had had two whiskies and a soda during the day, and was not under the influence of drink. The fact that he had eaten his dinner with only the slight discomfort of a stiff neck is extraordinary. A day or two later there was a small collection of pus in the region of the injury, but this, with fomentations and a spray of glycothymoline, soon cleared up, and he made an otherwise uninterrupted recovery.

The Etiology of Rickets.—L. Findlay refers to the various current theories as to the cause of rickets and passes on to consider especially the results following in animals from deprivation of exercise. His general conclusions are as follows: (1) Not one of the many theories which have been elaborated to explain the cause of rickets has been universally accepted, and they all lack, not only from the clinical but also from the experimental aspect, unequivocal proof. (2) It is some error in feeding which, in England and America, is commonly believed to bring about the disease, but it is doubtful, however, if feeding plays any important part in the etiology of rickets. Experimentally the author, like several other observers, has been unable to cause the conditions by improper feeding. (3) By confining young dogs and depriving them of exercise, rickets has been invariably induced, as in the experiments detailed, and that although their diet was beyond suspicion, the air which they breathed pure, and their kennels were kept scrupulously clean, whereas controlled animals allowed exercise, but otherwise similarly treated, did not become affected. (4) Examination of the conditions under which rachitic children are reared reveals one constant and invariable factor in their lives, namely, confinement. Alike, then, on clinical and experimental grounds the author concludes that confinement, with consequent lack of exercise, is the main factor in causing the disease.

Causes of Peritonitis During Pregnancy.—Clinical notes of a series of cases are given by A. Cuff. They present as causative factors appendicitis, with and without perforation, the pyelonephritis of pregnancy due to the infection of the upper urinary tracts by the colon bacillus, lead colic, etc. Other causes are torsion of an ovarian pedicle, red degeneration of uterine fibroids, etc. With reference to the appendix cases the author says that in view of the extreme likelihood of the disease running a dangerous course and the rapidity with which its stages are passed through, the appendix should be removed as soon as the diagnosis can be made in any case of pregnancy. If this be done in an early stage, the risk to the patient is slight and the prospect of the pregnancy being undisturbed is good. In no case should any attempt be made to empty the uterus with a view of influencing the appendicitis.

The Mental Nerve Area and Its Relation to Grayness of Hair.—G. L. Cheath says that this area is unique in that it is the nerve area which can be completely covered with hair, and in which, at the same time, there is so little overlap from other nerves. All other nerve areas are either more overlapped by neighboring nerves or they are not completely covered with hair. Hence the mental nerve area is the most interesting and instructive nerve area in the human body in which to study the incidence and spread of the hair's grayness or whiteness. The author then presents a series of photographs showing patches of grayness in the hair and beard. The points of incidence and the area of spread of grayness demonstrate to a certainty in his mind a neurotrophic cause for both. He adds that with regard to the incidence of neurotrophic diseases of the lower lip he has seen leucoderma, scleroderma, herpes zoster, etc., and he regards the blackish-yellow patches of pigmentation which appear on the skin and mucous membrane of people comparatively advanced in years as a neurotrophic lesion also. Such patches he has seen on the lower lip as well as on the temples, face, and the back of the hands. Occasionally cancer of the lip begins at the same time and at the same place as the lesions referred to, and this fact the author regards as favoring the view that the genesis of cancer is not due to the local action of an external organism, and that if it is due to the action of an organism it cannot be the sole cause.

Berliner klinische Wochenschrift, June 29, 1908.

Preparation of Diphtheria Antitoxin.—Blumenthal says that three factors are present in the preparation of antitoxins: the toxin, the technique, and the animal. The latter is not in our power to modify and the first two factors are to be so regulated as to nullify as much as possible the varying peculiarities of the third factor. It has been decided that the use of pure toxin is best in the production of antitoxin, the various chemical and physical methods of changing it before injection into the animal having been proved useless. Two elements are present in the technique of injections: the quantity of the toxin used and the site of injection. The conservative method consists in the use of progressively increasing doses of toxin, beginning with very small quantities and rising very gradually to the higher values. Such method gives most play to the individual peculiarities of the animal and is to be condemned. The heroic method consists in preparing the animal in a short time by small injections and then rapidly increasing the dosage to high figures. This has given best results in Blumenthal's hands. As to the site of the injections, the intravenous route has proved to be least adapted for the purpose; the subcutaneous and the intramuscular injections are most widely used and give good results. Still better results were obtained by the author with intrapulmonary injections of the toxin, by way of the intercostal spaces, the lung tissue being rich in makrophages (Mechnikoff), that have the power of absorbing toxins and producing antitoxins. Larger doses could be used by this method; the resulting antitoxins were more uniform in strength, thus showing that the varying factor, the individual peculiarity of the horse, was lessened, and the antitoxic value of the product was very high. The animals bore this method of injection better than other methods, the reactions being very slight and the loss of weight not large. The author gives two instances of such production of antitoxin, and says that his method is not at all comparable to intratracheal injections. In the latter the toxins are rapidly absorbed by the lymph vessels and transferred to the blood. Its value therefore is little more than that of the intravenous method.

Münchener medizinische Wochenschrift, June 30, 1908.

The Ophthalmoreaction.—Fehsenfeld has tried the Calmette test in 168 patients, twenty-five of whom came to autopsy. The findings agreed with the results of the test in 60 per cent. of the cases; in nine patients the results of the test did not agree with the condition as found post mortem. The ophthalmoreaction, accordingly, can only be looked upon as one corroborative sign of tuberculosis, but in no wise a deciding one. In the same number of the weekly, Hörrmann reports the results of his tests in cases of tuberculosis of the genitourinary system and warns against too early an enthusiasm in reference to the test. Goerlich reports cases of serious damage to the eyes caused by the application of the test, and concludes that the reaction should never be tried in the presence of any disease of the eyes, however light in character. Nursing infants and "scrofulous" children should also be exempted, while great care is necessary in the presence of inflammatory disease of the pharynx. He also warns against the use of the test in hypochondriac and hysterical subjects, in whom the positive result, which they can so easily observe and may know how to interpret, may have serious psychic effect. In conclusion, Goerlich says that, in general, the test cannot be recommended to the practical physician.

Suture of the Lung After Gunshot Injury.—Schütte says that conservative treatment in cases of severe

hemorrhage from the lungs due to trauma has had 40 per cent. mortality. Of the twelve cases treated by operation only three died. He reports a personal case of attempted suicide in which, in addition to two wounds of the head and brain, there was a bullet wound of the left chest, with very severe pulmonary hemorrhage. Immediate operation was performed, the lung being sutured with catgut, which stopped the bleeding immediately, though in the short time of its duration there escaped 1 1-2 to 1 3-4 liters of blood into the pleural cavity. Several hours later counter-incisions into the same pleural cavity were made and the skull and brain injury treated in the usual manner. Convalescence was slow, but at the end of six weeks the patient recovered; the injured lung seemed to have expanded completely. Schütte thinks that in such apparently hopeless cases of pulmonary hemorrhage due to trauma operation is indicated in preference to conservative treatment; paracentesis and aspiration alone cannot insure from a new hemorrhage or the continuation of the primary one.

V. Pirquet's Test in Nursing Infants.—Morgenroth has tried the v. Pirquet test in 200 nursing children brought for treatment to a clinic. Ten of them, that is 5 per cent., gave a positive reaction; eight came to autopsy and showed tubercular disease; in two others the diagnosis was assured clinically, though the autopsy was not allowed. No doubtful reactions were observed. The test was performed with the old tuberculin, proved to be free of all danger, and was not followed by any unpleasant consequences. It should be used, according to the author, in every case in which the history of exposure to tuberculosis of a nursing child brought for treatment is obtained. It ought to replace completely the subcutaneous test at this age.

Deütsche medizinische Wochenschrift, June 25, 1908.

Resection of Joints.—Müller says that formerly the technique of joint resections was eagerly discussed, but now simple asepsis answers all demands in this respect, and the questions under consideration involve indications for the operation. The following are the indications for partial or complete operation: Joint tuberculosis; total or partial ankylosis of the joint, including the forms due to fractures or dislocations; acute suppurative destruction of the joint with necrosis of bone; orthopedic conditions, including flail joints; some forms of acute osteomyelitis involving the ends of bones; cases of arthritis deformans, "chronic rheumatism" and the destructive forms of gonorrheal arthritis; primary resections following injury; tumors of the bones in case of very early diagnosis and comparative benign character of the new growth. The end always to be kept in view is the attainment of a movable joint and the means employed should consist in conservative operations, the smallest possible interference with the muscle apparatus, asepsis, and careful after-treatment. In the author's opinion complete suture of the wound is preferable to drainage in all aseptic cases including closed tuberculous abscesses. The risk taken is worth while, for the frequent primary union that takes place leads quickest to the attainment of a serviceable joint. A special point in technique is the use of instruments, not fingers, for all manipulations; operators using gloves need not change the technique in this respect.

Chronic Conjunctivitis.—Elsching says that the following causes are usually named in the etiology of chronic conjunctivitis: infection with specific microorganisms, the effect of toxins generated elsewhere in the body, eczema and seborrhea of the lids, inflammation of the lachrymal sac, affections of the nose and of the accessory cavities, various mechanical and chemical injuries, and the effect of bad light. The other well-defined forms of conjunctivitis are usually left out. One of them is usually confined to the conjunctiva of the lids and is caused by the inflammation of the Meibomian glands, out of which a great deal of purulent material may be obtained by pressure. The regular and frequent emptying of the glands by such pressure and light massage is the only procedure that offers a cure of the coexistent conjunctivitis, which is very chronic in character and proves quite obstinate under the usual methods of treatment. The second form of conjunctivitis is caused by the absolute or the relative insufficiency of the eyelids, which leave a portion of the eyeballs exposed in sleep. This condition is often responsible for a dry and thickened state of the conjunctiva, which is very apt to become inflamed on the least provocation. The use of a protective ointment or the application of a light bandage over the eyes at night hastens the recovery from the affection. In both forms of conjunctivitis described above compresses and various instillations are of little use; only the etiological therapy is successful.

Treatment of Puerperal Septicemia.—Otto v. Herff comes to the following conclusions at the end of an exhaustive article on the above subject: At the present time we are unable to destroy directly or indirectly the microorganisms that have entered the body in cases of "puerperal fever." The only internal medical treatment consists of general dietetic and hygienic measures. In the face of this condition of affairs the operative treatment ought to be more frequently resorted to, and such procedures as the ligation of the pelvic veins in order to prevent the spread of the bacteremia should be tried. Operative treatment is likewise indicated in cases of spreading peritonitis. The best procedure is the removal of the uterus if it is done early enough; the operation of choice consists in the supravaginal amputation of the uterus with thorough cauterization of the stump. Out of sixteen patients operated upon by this method eight recovered, the deaths occurring in late cases or where the complete operation advised by the author was refused.

French and Italian Journals.

A Case of Cerebral Traumatism.—Colucci describes the case of a peasant who received a blow on the head with a spade, causing a fracture of the right superior parietal region, with depression of the fragments. The injury resulted in insomnia, faintness, and attacks of Jacksonian epilepsy. The disturbances of cutaneous sensibility were remarkable. There was tactile hypoesthesia and lessened pain sense over one-half of the trunk, of the head and arm of the same side. There was a syndrome of cerebral localization that is unmistakable, the lesions of sensation remaining constant and proportional to the other disturbances. The Jacksonian epilepsy showed that the condition was not hysterical. The hypoesthesia increased and extended to the limbs in which the epileptic movements were found. This case is unique in literature. The author took the radial pulse and the cerebral pulse at the same time. He found that at the time of the Jacksonian attacks and before and after them there was a vasoparesis and probably cerebral congestion. In the radial pulse there was vasoconstriction.—*La Riforma Medica,* May 4, 1908.

Observations and Experiments on Serodiagnosis of Syphilis.—F. Micheli and L. Borelli have experimented on serodiagnosis of syphilis by means of an alcoholic extract of various body substances; the reaction has given 88 per cent. of positive results in florid syphilis of all conditions and degrees; in primary syphilis 83.3 per cent.; in secondary syphilis 96 per cent; in tertiary syphilis 77 per cent., and in tabes and paresis 79 per cent. In latent syphilis, recent or late, the reaction was positive in only 45 per cent. of cases. The results demonstrate that whatever be the nature of the reactive substance in luetic serum they are in direct relation to the quantity and activity of the syphilitic virus. The reaction is founded upon the disappearance of the complements which follows the mixture of an extract of luetic organs with the serum of a syphilitic. The alcoholic extract is to be preferred to a watery one because of its permanency. The examinations were made on 200 individuals, of whom 120 were certainly syphilitic or were suspected of it, and the rest were convalescents or affected by various forms of disease nonsyphilitic. These cases are tabulated. Negative results with the serum reaction do not exclude syphilis absolutely. Under energetic specific treatment the reaction may be seen to disappear in from thirty to forty days. Hence specific treatment seems to be effective in removing the conditions which render it positive.—*Rivista Critica di Clinica Medica,* May 9 and 16, 1908.

A Family Epidemic of Rubeola.—P. Aubert describes an epidemic of rubeola which was propagated in a single family to ten of its members, residing at a distance from one another, the beginning of the epidemic being involved in mystery. It attacked five persons who were in contact with the initial case; three remained in the country and two went to the city of Lyons. These two cases carried the contagion to five other persons. Of the ten patients four were adults and they had the disease more severely than the children. The affection was slight, accompanied by a low fever, and a slight sore throat. The glands of the neck were swollen. The eruption was diffuse, of a rose color, and appeared in red points that were separated by clear areas of skin, but not in crescents like measles. The eruption is difficult to differentiate from that of measles, but there is no cough or running of the nose; the prodromal period was from fifteen to twenty days. The chief differential signs from measles are the short prodromal period, absence of nasal and ocular catarrh, and the less intensity of the fever. This disease is somewhat rare in France.—*Lyon Médical,* May 10, 1908.

Book Reviews.

Religion and Medicine. The Moral Control of Nervous Disorders. By Elwood Worcester, D.D., Ph.D., Samuel McComb, M.A., D.D., Emmanuel Church, Boston, and Isador H. Coriat, M.D. New York: Moffat, Yard & Company, 1908.

Much has been said and written of the Emmanuel movement, of the attempt of the clergymen of that church in Boston to cure functional nervous diseases by means of suggestion, and several imitators or followers of these Episcopal clergymen have already arisen among ministers of their own and other sects in other cities. Some of these followers have grasped the meaning and aim of the movement and are imitating the methods of the Boston clergymen and observing the limitations which they have set to their therapeutic endeavors; others, unfortunately, seem to see in it only a modified Christian Science or faith cure, and are throwing out their drag-net to bring in the halt, the maim, and the blind, and those possessed of demons, professing to make the maim to walk and the blind to see, and casting out devils in the name of the Lord. This is the great danger and the evil of a movement such as the one initiated by Dr. Worcester. Laymen, in medicine and in religion, are often more logical according to their lights than the professed; but their lights are less, and they fail to see the limitations to reason which faith imposes in the one case and the limitations to healing which science imposes in the other. In medicine they reason, with apparent logicality, that if constipation and insomnia and the drink habit can be cured by suggestion, equally ileus and insanity and other organic diseases should be amenable to mental treatment. For such as these, therefore, an authoritative description of the Emmanuel movement will be of service, and the book will be welcomed also by physicians who have been doubtful of the motives of its originators and have suspected them of encroaching upon the functions of the medical man. We are not sure that a perusal of the book will entirely disabuse their minds of this suspicion, but it will at least convince them of the sincerity of the writers. Dr. Worcester states that the work from the beginning has been done in association with physicians, and that everything that has been done has been with their cooperation and advice. The basis of the work is suggestion and a training in the practice of autosuggestion, and as yet only those patients are treated who are pronounced by the medical associates in the work to be suffering from purely functional diseases. The cures are attributed to Divine action, but to the objection that God's power is not limited and that if He can cure functional nervous diseases He can equally cure organic affections, the very sane reply is made that God has power to cure all diseases, but He does not cure all disease in the same way. The authors of the movement therefore content themselves with invoking His aid in only one class of diseases, and leave the management of disorders having a material basis to those whose knowledge and training qualify them for the application of physical remedies.

The chapters on Prayer and on the Healing Wonders of Christ are interesting in a popular theological sense. Prayer, in the view of the writer, a clergyman of the Episcopal Church, is in the nature of suggestion, working upon the Divine mind in such a way as to direct it more powerfully and more constantly to the object prayed for. Concerning the miracles of Christ, we are led to believe that they were effected through suggestion, and that the diseases cured were nervous and not organic affections at all. Christ Himself, however, it is implied, did not know they were purely functional nervous diseases, and so was deceived in regarding Himself as possessed of greater healing powers than He had or at least than He exercised. This is surely not Episcopal teaching, but it is interesting.

To return to the medical aspect of the book, however much we may disapprove of the Emmanuel movement we can but welcome its apologia as presented in this volume. We believe it would be better for medicine and better for theology if the practitioners of each confined themselves each to his own field of usefulness. Nevertheless it is good for medicine to get a jolt occasionally by witnessing cures obtained in an entirely unauthorized way. The bone-setters, the Christian Scientists, the hydropaths, the osteopaths, the nature healers have all taught us that man does not get well by drugs alone, and a repetition of this lesson given by the sincere, modest, and sane authors of the Emmanuel movement will be good for us. "Religion and Medicine" should be read and studied by every medical practitioner. He will be interested and he will be instructed, and if he takes its lessons to heart he not only will have increased his therapeutic horizon, but will have got a hint regarding his own improvement—mental, moral, and physical.

Borderland Studies. Miscellaneous Addresses and Essays Pertaining to Medicine and the Medical Profession, and Their Relation to General Science and Thought. Volume II. By George M. Gould, M.D., formerly Editor of the *Medical News*, the *Philadelphia Medical Journal*, *American Medicine;* Author of a Series of Medical Dictionaries, "Biographic Clinics," "Concerning Lafcadio Hearn," "Righthandedness," etc. Philadelphia: P. Blakiston's Son & Co., 1908.

This is a collection of essays on various subjects, medical and sociological, most of which have been published in medical and other journals and are now brought together in permanent form for convenience of reference and study. One of the most interesting chapters is that entitled "The History of the House," in which the erudite author traces the development of our present form of dwelling from the rude shelter for cattle and the bent sappling tent from which man got his idea of a convenient habitation for himself, and several of the features of which are to be traced in the architecture of to-day. In "The Seven Deadly Sins of Civilization" Dr. Gould treats of the consumption of tobacco, alcohol, sugar, tea and coffee, venereal diseases, the modern house, and eyestrain, which he contends act much more injuriously upon all classs of the population than they did in ancient times and to the effects of which he attributes many of the diseases of modern man. Among the other topics entertainingly discussed are "Child Fetiches," "King Arthur's Medicine," "History and Psychology in Words," and "Vocation or Avocation," all of which in varying degree command the attention of the reader, whether or not he agrees in all particulars with the author's statements and conclusions. The book is one that will well repay reading in one's leisure moments, and will provide food for thought without taxing the brain with too serious problems.

Concerning Lafcadio Hearn. By George M. Gould, M.D., with a Bibliography by Laura Stedman. Philadelphia: George W. Jacobs & Company, 1908.

In this book Dr. Gould has brought to bear upon the baffling personality of its subjects a quite unique equipment for the purposes of elucidation. In the first place he had a close personal acquaintance with Lafcadio Hearn, gained in the months when they lived together in the relation of guest and host, and to have a man under one's rooftree is surely the only royal road to knowledge of him. In the next place Dr. Gould brings to his task a native gift of psychological insight, and that the psychology of Lafcadio Hearn presented a hard nut to crack is proven by the storm of conflicting claims for him and statements about him since his death, from friends and enemies alike. Last, but not least, the great value of this book to the medical profession is its close analytical exposition of the connection between Hearn's physical disabilities and his genius as a writer. Dr. Gould has given the world five volumes of his carefully reasoned out Biographic Clinics, he has drawn the web of his close and seemingly incontrovertible argument around so many of the mentally great, around musicians, writers, poets, men and women who have achieved much, and whose names will never be forgotten, and yet who accomplished their lifework under one bitter handicap common to them all—the handicap of eyestrain. In "Concerning Lafcadio Hearn" he has written one chapter, "The Poet of Myopia," which must surely be of interest even to those unprepared to grant its entire claim. "Intellect," says Dr. Gould, "is largely, almost entirely, the product of vision—especially the esthetic part of intellect." Is it? one wonders, and wondering, one reads on, only to become helplessly beguiled by the spell of Dr. Gould's single-hearted faith in his theory and by his wonderful style. The book is intensely interesting, and the chapter on "Appreciation and Epitomes" and the Bibliography are of enormous value to anyone desiring to know Hearn the writer, and to study the development of his wonderful literary genius which triumphed so signally over the fearful obstacle of almost complete blindness.

An Aid to Materia Medica. By Robert H. M. Dawbarn, M.D., Professor of Surgery and Surgical Anatomy, New York Polyclinic Medical School. Tenth Edition, Revised and Enlarged by Eden V. Delphey, M.D. New York: The Macmillan Company, 1908.

The aim of this little work is said to be the presentation, in brief space and tabular form, of all the drugs and preparations recognized by the present Pharmacopœia, with their doses expressed in both apothecaries' and metric systems; also the exact composition and strength of all preparations. Synonyms, pronunciation, and, in the case of drugs of vegetable origin, the derivation and habitat are given. The description of a number of the more commonly used nonofficial preparations is also given. As a work for ready reference and for refreshing one's knowledge of materia medica we can recommend this book.

Society Reports.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held March 16, 1908.

The President, Dr. Robert T. Morris, in the Chair.

Report of the Committee on the Death of Dr. F. Ferguson.—Dr. Hubert Arrowsmith, chairman.

A Case of Fracture of the Ischium from Indirect Violence.—Dr. A. W. Jagger of Flushing, L. I., showed this case, together with *x*-ray pictures. The patient was a man of fifty, who in the summer of 1907 had a fall which gave rise to a good deal of pain in the gluteal region, and which incapacitated him for three days. After that he was apparently as well as ever. In January, 1908, while walking on the street, he stumbled, and, despite a violent effort to regain his balance, he fell prone at full length. Upon rising, he experienced a sharp pain in the upper and inner aspect of the left thigh and gluteal region, which compelled him, when he reached his destination, to sit on the edge of a chair. When Dr. Jagger saw him on the following morning, the thigh was partially flexed and very painful. Upon grasping the muscles on the inner aspect of the upper thigh, and making pressure over the insertion of the adductor magnus, distinct crepitus was obtained, and an *x*-ray picture confirmed the diagnosis of fracture of the ischium. The patient remained in bed for two weeks, and made a good recovery without further treatment.

The Relations of Tabes and Paresis.—Dr. J. Ramsay Hunt presented this paper, which was the first of a series on progressive locomotor ataxia. The writer stated that in the whole chapter of locomotor ataxia there was no question of greater importance than the relation which this affection bore to the general paralysis of the insane. The importance of this relation was not merely a clinical one, but had a much deeper significance as touching upon the underlying nature and etiology of the two diseases. As was well known, tabes dorsalis was a disease characterized by degenerative changes in the posterior roots and posterior columns of the spinal cord. The essential etiological factor in the production of this degeneration of nerve structure was antecedent syphilis, a history of which was present, as variously estimated, in from sixty to ninety per cent. of the cases. This was not syphilis in the ordinary acceptation of the term, but was presumably a toxic state following in its wake—the so-called parasyphilis, or metasyphilis. Paresis, on the other hand, was a degenerative affection of the cerebral cortex; of the association and projection neurons of the brain. It bore the same etiological relation to antecedent syphilis as did tabes, a specific history being present, according to Mendel, in seventy-five per cent. of the cases. This relation to syphilis constituted an important bond of union between the two affections. So close had this relation appeared to Moebius that he termed paresis the tabes of the brain, and no less an authority than Fournier had said of tabes that it was not an affection of the spinal cord alone, but one of the cerebrospinal axis. The clinical course of events in the development of tabes and paresis might be as follows: Symptoms of locomotor ataxia might appear first, the affection running its usual course, and the symptoms of paresis supervening. Such paretic symptoms might develop within a few months, or might not appear until after the lapse of many years. In rare instances as long a period as twenty years had elapsed between the onset of the tabes and the first symptoms of dementia paralytica. On the other hand, the case might begin as one of paresis, the tabetic symptoms developing subsequently. In not a few of the cases paresis and tabes began simultaneously, and ran their course together. Taboparesis occurred so frequently that the combination could not be regarded as an accidental one, or as a mere coincidence. Nageotte found that two-thirds of his cases of paresis presented signs of locomotor ataxia; Shaffer found the same complication in three-fourths of his cases. Binswanger, who was somewhat stricter in his interpretation of what constituted a tabes with paresis, recorded the complication in one-fifth of his cases. These statistics were not based upon tabetics who developed paresis, but referred to cases of paresis in which symptoms of locomotor ataxia were present. The proportion of cases of tabetics developing paresis was certainly very much smaller. In the Nervous Clinic of the Cornell University Medical College, during the past six years, there had been treated 164 cases of locomotor ataxia; of this number only sixteen presented the mental or somatic symptoms of general paresis. The pathology of taboparesis had been the subject of much investigation and considerable controversy. After reviewing this at some length, the author concluded with the statement that tabes, paresis, and taboparesis did not differ essentially in etiology, nature, or pathology, and that all possible transitions and combinations of the spinal cord and cortical localization were found clinically.

Laryngeal Involvement in Tabes.—Dr. Wolff Freudenthal, in this paper, said that for the past three years he had been examining the throats of all the cases of locomotor ataxia at the Montefiore Home and elsewhere, and as the result of his experience he had come to the conclusion that laryngeal disturbances were much more frequent in tabes than had been heretofore believed.

The Bladder in Tabes.—Dr. J. Bentley Squier, Jr., said that the importance of a thorough appreciation of the rôle which motor or sensory irregularities of the urinary vesical function played in the diagnosis, course, and termination of posterior spinal sclerosis could not be overestimated. A certain percentage of tabetic patients had their attention directed to disturbances in their urinary function as the primary discomfort. The percentage was not particularly large, but the number was sufficient to emphasize the fact that the possibility of tabes should be kept in mind in diagnosticating any case of unusual functional disturbance of the bladder. If in 80 per cent. (Starr) of tabetic patients bladder symptoms were present, and in 30 per cent. (Erb) of these they formed the initial symptoms, the value of this statement was manifest. It was not uncommon for the genitourinary surgeon to have a case of tabes brought to him for diagnosis or treatment where, from the symptoms only an organic bladder or prostatic lesion had been suspected. The differential diagnosis being often difficult, such an error was easily explained. Even though the patient had tabes, he might also have a local lesion which was in part or wholly responsible for the bladder symptoms. *Vice versa*, if the cord lesion was present, but unrecognized, one might inadvertently propose some radical surgical measure for the relief of the urinary symptoms, presumably due to local causes, but which were in reality due to a central lesion, thus leaving the patient in a more distressing condition than he would have been if no operation had been performed. Bladder symptoms in tabes, when present, usually presented themselves as (*a*) varying degrees of retention of urine, or (*b*) varying degrees of incontinence of urine, in accordance with the degree of interference in the reception of sensation to the mucous membrane, or of the muscle of the bladder. The vesical symptoms might be so slight as to escape the patient's notice, or he might have some hesitancy in commencing micturition. When the desire to urinate occurred, he might be unable to control it, and a few drops might escape before he could reach the toilet. In laughing, coughing, or during sleep there might be slight incontinence, or he might have absolute incontinence or absolute retention. Any of these symptoms might be wholly due to the central lesion. On the

other hand, if infection of the urinary tract took place from septic instrumentation or autoinoculation, all the other symptoms of cystitis, prostatitis, vesical calculus, and pyelitis might be added. Having eliminated all other pathological conditions which might be present in a tabetic bladder or adnexa, the question of treatment resolved itself into a two-fold proposition: First and most vital, to keep the viscus in an absolutely sterile condition. Second, to reestablish, by motor reeducation, its lost function. The first proposition was a surgical probability; the second, an experimental possibility. The patient should be taught the value of making efforts of urination at stated times and always to try to evacuate the bladder to the last drop. Sometimes instillations of silver nitrate solution could be used in the prostatic urethra with beneficial results. If it became necessary to put the patient on catheter life, no detail in his instruction in sterile catheterization should be overlooked, as upon that might depend the extent of his lease of life.

Present Methods of Treatment of Locomotor Ataxia.—Dr. S. Wachsmann discussed this phase of the subject. He said that, starting from the overwhelming frequency of clearly syphilitic cases of tabes, we had been in the habit of repeating an antisyphilitic course of treatment, and even in those cases without a decided syphilitic history, we usually gave the patient what we called "the benefit of the doubt," but we would be obliged to admit that the "benefit" was mostly imaginary, and, so far as the speaker's experience in the Montefiore Home went, he was not prepared to state with any degree of accuracy that mercury or atoxyl had ever stayed the process or produced an appreciable improvement in the patient's condition. Besides the antisyphilitic cure, there were very few means of attacking the process, and those were mostly of a nature that tended to tone up or strengthen the constitution, and in that way enable the system to stave off the progress of the disease. The methods the speaker had in mind were the hydriatic and the electric treatment. Of all the electric applications, it seemed to him that sparks of the static machine were followed by the best results, and he thought there was no doubt that both the hydriatic and the electric treatment had repeatedly given at least temporary relief and the process became stationary for a considerable number of years. Massage was contraindicated in all cases of locomotor ataxia, and when given by the strenuous advocates of that art it had produced tears in the muscles and other accidents. The trophic lesions were either ulcers or changes in the joints, and they required either surgical or orthopedic treatment. For the shooting pains the coal tar products, antiyprin and acetanilid, in combination with caffein, seemed to be the most efficacious. For the girdle pains, the sensation of bands or the vise-like pains and the various neuralgias as well as intercostal pains, the salicylates were apparently most satisfactory. Heat and cold usually had the best effect when used in the form of hydriatic applications; some patients were more relieved by hot water; others by cold. The gastric crises were treated with the best success by giving repeated doses of cerium oxalate, two or three grains, with external applications of heat, and, if possible, by lavage. For the explosive diarrhea occurring in the course of the intestinal crises, opium in the shape of suppositories gave the best results, but the liberal use of opiates should be avoided in a chronic disease of this nature. The very troublesome urinary incontinence the speaker had seen improved in one or two instances by lumbar puncture. The eye symptoms, muscular palsies, and optic atrophy, were usually treated by strychnine and large doses of iodides. The ataxia or incoordination could not be treated by drugs, but was beneficially influenced by total abstinence from tobacco and alcohol. The actual treatment of this symptom was a systematic development of what was left of the deep muscular and articular sensibility. Efforts in that direction had been made by various authors, but the best results had been obtained by an elaborate and very ingenious system of reeducation which had become known under the name of its originator as the Frenkel (Heiden) method.

Dr. Edward A. Fruchthandler showed two patients from the Montefiore Home who were suffering from advanced tabes, and whose ataxic symptoms had markedly improved under the Frenkel method of teaching.

Dr. A. D. Rockwell said that the Frenkel method of treating the ataxic symptoms of tabes was undoubtedly the brightest spot in the therapeutics of that affection; aside from that, the results of other methods of treatment could not be regarded with any degree of enthusiasm. In speaking of the causation of the disease, Dr. Rockwell said it must be conceded that the chief causative factor was syphilis, and in an analysis of a large number of cases made by him more than twenty years ago he had found that between 80 and 90 per cent. of the patients gave a syphilitic history, and since that time he had scarcely seen a case in which such a history was not obtainable. In fact, he felt almost like agreeing with Gowers and others that syphilis was the invariable cause of tabes, and yet he did not care to go quite so far, for he had seen cases in women in whom it was practically impossible to associate the disease with syphilis. However, if we could subject all our syphilitic patients to a thorough and early course of antisyphilitic treatment by modern methods, we would doubtless see much less locomotor ataxia. While we were unable to do much in the way of curing these patients, or even retarding the progress of the disease, we could in many cases relieve their symptoms. The use of the static spark, to which one of the speakers had referred, Dr. Rockwell regarded as utterly useless in the way of retarding or greatly benefiting the disease, or even for the relief of pain. The two physical methods that he had found particularly beneficial in these cases were the use of the galvanic current, and the application of light and heat, especially the latter. By this he referred to the use of the incandescent or arc light, which apparently exerted a distinct influence on the circulatory apparatus. Some patients received more benefit from the galvanic current; others from the effect of the arc light. Suspension was another method which in some cases he had found distinctly beneficial. Some years ago, the speaker said, he was induced to try ultraviolet rays in a few cases of long-standing locomotor ataxia, but with absolutely no benefit.

Dr. W. B. Pritchard said that, while it was difficult to completely cover in one evening's discussion a subject which was so protean in its aspect as locomotor ataxia, he was inclined to agree with the exceedingly conservative, and, at the same time, very complete presentation made by Dr. Hunt, whose paper embraced an accurate epitome of the consensus of views that prevailed among neurologists and syphilologists to-day. In medical literature to-day the question was frequently raised whether paresis was ever a curable disease. Whether it was curable or not, there was no doubt of the fact that the clinical picture of paresis was changing; that the duration of the disease was in many instances longer, and that the grandiose ideas with which it was formerly invariably associated were often wanting. If these changes were occurring in the clinical story of paresis, why could not the same be true of tabes? If we occasionally met with bizarre and aberrant types of paresis, the same was true with much greater frequency of its first cousin, tabes. Dr. Pritchard said he was absolutely sure that he had seen cases of tabes dorsalis in which the theory of syphilis, as an etiological factor, was untenable, and he strongly wished to dissent from the assertion which had been made that if the story of syphilis had never been written, that of tabes dorsalis would never have been read. In reference to Dr. Freuden-

thal's paper, the speaker said that, in his experience, laryngeal crisis was an exceedingly rare occurrence in tabes, and he could recall only three cases in which distinct laryngeal crises had occurred. Perhaps a more systematic and thorough examination of the throat in these cases would result in finding a larger proportion in which such a complication occurred. In the general treatment of tabes dorsalis, he wished to emphasize the importance of the personal equation; the same remedy did not apply to all cases. The Frenkel method, while a monumental piece of constructive work, especially in its careful attention to details, was too elaborate and scientific to be followed in routine practice.

Dr. H. G. Piffard said the static spark, while it sometimes relieved pain, might in itself give rise to considerable pain. The speaker said that in the *New York Medical Journal* for June 16, 1906, he had reported two cases of locomotor ataxia treated by high frequency currents, and described in detail their methods of application. The first case was that of a man fifty-three years old, in whom the disease had advanced to such a degree that he had been obliged to give up business, both on account of his ataxia and mental failure. When treatment was begun, he was unable to walk unassisted, and he was brought from his home in a cab, although he lived but two blocks away. At the end of two months' treatment with the high frequency currents, his pains were markedly ameliorated, he could walk to and from his house with the assistance of one cane, and was able to close up his business affairs. He subsequently went to Europe, where he was advised to go to Switzerland and consult Frenkel. Besides the electricity, he took thirty grains of sodium iodide daily for a short time. The second case was in a man about forty years old, whose ataxic gait was scarcely noticeable, excepting to himself. The tendon reflex was absent; no Argyll-Robertson; there was marked hypotonia of the muscles of the lower limbs, and Babinski reflex; occasional but not very severe pains. He received three treatments a week for two months, at the end of which time the ataxic gait had greatly improved, the pains had for some time been absent, his general health was much better, and he was able to give better attention to his business. The treatment was by autocondensation. In this case, iodide was not well borne, and had to be discontinued after two weeks. Dr. Piffard said that in view of the superficial action exerted by the ultraviolet rays, to which one of the speakers had referred, it was hardly credible that they could influence the tissues of the spinal cord, even when given with the aid of adrenalin.

Dr. William M. Leszynsky, referring to the diagnosis of locomotor ataxia, thought that any general practitioner who had ever seen a well-developed case could scarcely fail to recognize the disease thereafter. There were borderline cases, however, in which the diagnosis was not so simple, and in those instances where cures had been reported by electricity or other means after the disease had existed for years he had always been inclined to doubt the correctness of the diagnosis. The speaker referred to the futility of putting these patients through repeated courses of antisyphilitic treatment, and called attention to the fact that mercury and the iodides did not influence the antibodies in the syphilitic poison which were regarded as an etiological factor in tabes. Dr. Leszynsky said that tabetics were very susceptible to suggestion, and he emphasized the importance of that factor in the treatment. The digestive tract should also receive careful attention, especially in connection with the tabetic pains. The Frenkel method of treating the ataxia was excellent, but could not always be satisfactorily carried out excepting in institutions.

Dr. Fruchthandler said he had treated several patients alone with excellent results. All that was necessary was a large room and a good working knowledge of the method.

Dr. Hunt, in closing, emphasized the occurrence of syphilitic pseudotabes and pseudoparesis forms, which very closely resemble the true tabes and true paresis; so closely, in fact, that sometimes an absolute diagnosis could only be made by observing the effects of antisyphilitic treatment. This fact may explain the cases of tabes that respond to antisyphilitic treatment. We must recognize parasyphilis, and the more active form of syphilis of the central nervous system; the latter would respond to antisyphilitic treatment, whereas parasyphilis would not. The speaker said he was quite in accord with Dr. Pritchard that there were cases of tabes in which no history and no symptoms of an antecedent syphilis could be obtained, yet we could never be absolutely certain on that point, in view of the often insignificant nature of the primary lesion and the latter signs, and the nature of the disease itself, which naturally made many persons very secretive regarding it.

Dr. Wachmann, in closing, said that many tabetic patients in the course of time became more or less neurasthenic, and were perhaps inclined to exaggerate their pain. In those cases, especially, the shocks from the static machine had proved very serviceable. While the galvanic current was usually given preference in the treatment of locomotor ataxia, no reliable results had been obtained from it. The speaker said he did not employ electricity in these cases to stay the process, but only as a symptomatic remedy. With the static machine it was not necessary for the patients to undress, which was a time-saving factor in handling a large number of cases. In many cases it certainly relieved the patient's pain, perhaps through its psychic influence, as the patient was doubtless somewhat impressed by the size of the machine, and the sound and sight of the spark.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held March 6, 1908.

Dr. Charles H. Peck in the Chair.

The meeting was held in Hosack Hall, and was devoted to a symposium on aneurysm.

Treatment of Popliteal Aneurysm by the Reconstructive Method.—Dr. J. F. Binnie of Kansas City said that since Matas' paper on endoaneurysmorrhaphy was read in 1902 before the American Medical Association much attention had been devoted to this subject. He did not intend to attempt to cover the whole field of the subject of aneurysm, but confined himself to a consideration of the possibility of obliterating the aneurysm and at the same time reconstructing the artery in such a fashion that the circulation through it might be restored. If a fusiform aneurysm was ever the result of direct injury to the vessel without there being preexistent disease of the wall, it must be extremely rare. The development of an aneurysm was generally to be referred to some series of strains acting on a vessel whose strength had been diminished by preexisting disease. Laboring men were the usual victims, and in about 80 per cent. of the cases a history of syphilis was present. Atheroma was commonly and vaguely accused of being a predisposing cause of aneurysm, but atheroma was most marked in the aged while aneurysm seemed to prefer victims of from 30 to 50 years. While the popliteal artery was a favorite site of aneurysm, it was not a common site of atheroma. Pierre Delbet with Eppinger believed that the cause of aneurysm was mechanical injury causing rupture, especially of the middle coat. It seemed that while an artery as a whole might be diseased and somewhat weakened, yet one very limited area thereof was so much more affected either by the disease or by concomitant injury that it gave way while the rest of the vessel remained capable of discharging its functions satisfactorily. If these arguments were in accordance with

fact, then it was reasonable to suppose that if sufficient arterial wall was left to reestablish the arterial tube and this arterial wall, though probably diseased, was not too much degenerated, then it might be possible safely to close with suture the communication between the artery and sac. In the case of a fusiform aneurysm nothing short of excision of the diseased segment of artery and end-to-end anastomosis of the more or less healthy arterial stump, or the implantation of a suitable segment of vein, could be of any conceivable value. The reconstructive operation of Matas seemed to him to be out of the question under such circumstances. In the sacculated aneurysm, provided the opening between the vessel and the sac was not too wide, a reconstructive operation might give good hope of success. He said he had used the method originally outlined by Matas in two cases. In the first he did not recognize at the time that he was doing a so-called reconstructive operation. He closed the single small opening into the sac with catgut and then obliterated the sac by rows of sutures. The second case was one of ruptured traumatic aneurysm, in which he obliterated the sac by means of continuous catgut sutures, the communication between the artery and sac having been closed by iodized catgut sutures. In both of these cases and in a similar one he saw with Dr. Frick, the results as regards cure of the aneurysm was good, but in none could it be proved that the circulation was reestablished through the vessel. Each of these cases seemed suitable for attempts at reconstruction, but the technique employed outraged every one of the principles elaborated by Carrel and was foredoomed to failure. In a third case he endeavored to utilize the principles of modern arterial surgery. In this case the operative technique used differed from Carrel's in that freshly cut arterial wall was not approximated, but two endothelial lined surfaces were brought together as in Dorrance's method of arteriorrhaphy by eversion. The artery as a whole was very seriously diseased. The result of the operation was a failure but a failure which came near being a success. The closure persisted for two weeks and then only about one-third of the line of union gave way. The case was most unfavorable; the arterial wall was markedly degenerated; the line of suture was absolutely unsupported by surrounding structure and laid exposed in the cavity of a false aneurysm, and yet apparently success was nearly attained. This failure encouraged one to hope that under more favorable circumstances success might be confidently expected and that perhaps in some cases of sacculated aneurysm of the abdominal aorta, it might be possible to open the sac, close the opening in the aorta, support the line of suture by obliterating the sac by means of sutures, and so make the weakest point in a weak aorta as strong as the rest of the vessel.

Personal Experience with the Modern Method of Treating Aneurysm.—Dr. Robert Abbe read this paper. Thirty odd years ago it was considered safest to cure an aneurysm by arresting the blood current by digital compression for a sufficient time to fill it with solid clot. Subsequently, antiseptic ligation held the field almost exclusively. The one idea that dominated the whole teaching of treatment was the successful filling of the sac by clot, which subsequently organized and shrank. Ten years later the theory of stiffening and thickening the resisting wall of the sac by induced inflammation and cell proliferation was advocated. The theory of building up and fortifying the wall from within soon became accepted as an available method. In 1886 and 1887 the introduction into the sac of silver and steel wire was advocated to induce clotting and to irritate the sac lining. About the same date puncture of the wall by electrolytic needles had many advocates. Proliferation of the endarterial coats was the keynote of success in these methods. Two facts were demonstrated by these contributions to the surgical knowledge of aneurysm: (1) That the sac wall, if irritated, could be made the important factor in curing aneurysm; (2) that where the tumor was large, the endarterial lining was considerably replaced by cellular tissue wall, and the thinned out lining was too far gone to be available, and failure by such method was sure. Loreta's case of aneurysm of the abdominal aorta prepared the surgical world to receive the new method of Matas which Dr. Abbe first employed in May, 1905, in a popliteal aneurysm of considerable size. This patient was perfectly cured without the slightest peril to the circulation of the foot. The second case was that of a young Russian of twenty-four years who had had for three months right sciatic neuralgia with disability in walking and some swelling of the foot. A pulsating tumor of the right gluteal region prevented his lying on that side. Examination revealed a spherical, pulsating tumor, three inches in diameter, beneath the gluteus muscle at the sciatic notch, where its pressure had caught the sciatic nerve, and held it tightly against the bone, causing the neuralgia. This was a particularly good case for operation by the plastic method. The patient made an immediate recovery after operation. This was a beautiful illustration of the reliance to be placed on the plastic union of opposing walls of an artery held in contact and irritated by the needle puncture and thread. The patient had no recurrence of tumor or sciatic pain up to three months after operation. It was his conviction that this method could be applied to any artery up to the size of the innominate.

A Case of Popliteal Aneurysm Presenting Unusual Difficulties to the Application of the Matas Operation.—Dr. Joseph A. Blake reported this case in detail. The operation was considered as a partially obliterative and restorative one, in that the proximal communication with the aneurysm was closed while the continuity of the vessel below that point was restored. He said it was a question whether a typical restorative or reconstructive operation was indicated for popliteal aneurysms since the constant flexing of the joint submitted the vessel to much traumatism. It seemed to him on theoretical grounds that the obliterative operation was better.

The Serous Coat of Blood-Vessels Compared with the Peritoneum.—Dr. Robert T. Morris said that the new work in the field of aneurysm brought prominently before them the fact that the serous coats of blood-vessels acted very much like the peritoneum. They adhered promptly when brought into close apposition; they poured out plastic lymph which quickly became replaced by connective tissue, and covered by new endothelium, just as the same process occurred in peritoneal reparative processes. The quick response of the serous coats made successful suturing of blood-vessels possible; and septic processes of these coats acted very much like septic processes of the peritoneum. From a practical standpoint he said it might be assumed that endothelial proliferation was quite as important in carrying on repair in blood-vessels as it was in the peritoneum. Silver wire and other substances introduced into the cavity of an aneurysm probably acted precisely as they would in the peritoneal cavity, by causing an exudation of coagulable lymph from the serous coat, leading to adherence of the endothelial walls. Manual pressure upon the walls of an aneurysm probably did the same thing, and the coagula which occurred probably began as lymph coagula, formed in response to irritation of the serous surfaces. It was this new conception of the serous coats of the blood-vessels acting like the peritoneum that had led surgeons to apply to this work the older principles which they had obtained from their work with the peritoneum.

Dr. Robert F. Weir said that he had had no experience in this reconstructive method of treating aneurysms. It seemed to be a fascinating department in surgery. From the time of Hunter, the ligature treatment of popliteal aneurysms was one of the most noted in surgery. From that time on the treatment of popliteal aneurysms received very marked attention. During the latter part of the last

century Esmarch's method was brought forward, making compression on the artery with the foot elevated, and with notable success. For awhile the ligature method was thrust aside, but resumed its sway under the antiseptic methods, and had remained in force up to the present. One of the most notable procedures was the extirpation of popliteal aneurysm, and Curtis of New York did this with the most happy results. He said that all operations for the cure of aneurysms, including the Matas method, were full of errors, and he always believed that the Matas operation was not likely to hold a place against the ligature method. However, it might be used with benefit in aneurysms at the root of the neck.

Dr. B. Farquhar Curtis said he had never tried the Matas operation, and he only consented to join the discussion because it appeared to him that we were in danger of trying to do experimental work without having much regard for the real cure of the patient. Patients wished to have their aneurysms cured. The majority of the cases of popliteal aneurysm could be cured safely and simply by ligation of the superficial femoral; gangrene or relapses were not common following this operation. If he felt that recourse must be had to a more extensive operation, he preferred extirpating the sac. In the ordinary soft-walled popliteal aneurysm this procedure did not seem to him to be indicated. Dr. Curtis said he had extirpated the sac in popliteal aneurysm on three occasions, once an aneurysm in the axillary space and once when the aneurysm involved the femoral. In many cases extirpation of the sac was quite as easy an operation as opening the sac and suturing the openings on the inside of the sac. The reconstructive method he thought to be worthy of trial in certain cases.

Dr. Arpad G. Gerster believed that we already had a good method of treating these aneurysms. As this reconstructive method was still *sub judice*, he thought it wise to employ it only in cases in which it was strictly indicated; he advised against its indiscriminate employment. Dr. Gerster brought forward a very curious fact. Twenty-five years or more ago aneurysms occurred in his hospital experience with comparative frequency, while now they had become rarer and more rare. And this was particularly true in the hospital with which he was connected, the Mount Sinai. It was certainly curious that within the last five years he had seen but one case of aneurysm. A gypsy violinist was shot when in flight from a wedding; a traumatic aneurysm of the gluteal artery was the result. In the Hebrew race aneurysms were extremely rare, and he believed this to be due to the fact that this race had early marriages, and so lessened the chance of syphilitic infection. Then, too, the rite of circumcision caused a toughened glans penis, thus making the danger of syphilitic infection less than in those not circumcised. The majority of the people of this race were employed in trades and occupations which did not require much physical exercise. This probably explained why so few aneurysms were met with at the Mount Sinai Hospital. Dr. Gerster had treated two cases of thoracic aneurysm by introducing long pieces of piano wire. Both of the patients died, not in consequence, but in spite, of the operation. One patient survived for a period of three months, the other for six months. The autopsy was consented to in only one; the wire formed a loose ball, and in the meshes was found a rudimentary coagulum.

Dr. John A. Wyeth said that aneurysm of single arteries was one of the gravest surgical lesions, and the gravity was in general proportion to the nearness of the tumor to the heart. When either the brachial, femoral, or popliteal artery was involved, the procedure of Matas would in many instances be found to be an ideal procedure. Reconstructive arteriorrhaphy might find its place in dealing with axillary or subclavico-axillary aneurysms, when only the third part of the subclavian was involved, but if possible less dangerous methods should be first essayed. In right subclavian aneurysm it was better to treat by distal ligation of the right carotid as a primary operation, to be followed by distal ligation of the subclavian in its third division or lower down in the axilla if the subclavian was diseased, and later, if necessary, by excision of the inner half of the clavicle. The ligature of the right carotid not only aided coagulation by throwing the retarded current back upon the innominate, but guarded against the accident of embolism. Aneurysm of the innominate should be treated in the same manner. Aneurysm of the carotid artery should, when possible, be treated by ligation upon both sides of the tumor, the distal ligature being first tightened to prevent the possibility of clot being carried to the brain. Aneurysm of the primitive carotid near the innominate or near the arch of the aorta, must of necessity be treated by distal ligature. Aneurysms of the internal carotid he had treated successfully by tying the common trunk at the birfurcation, and the external carotid artery at the same point. This insured stagnation between the ligature and the circle of Willis. Aneurysms of the external carotid he had treated successfully by ligating this trunk at its origin from the primitive carotid. Aneurysms of the ascending segment of the aortic arch offered great difficulties in treatment. He had tied simultaneously the right carotid and the right subclavian, with the result of solidification in a large spherical aneurysm over three inches in diameter. This patient died a year later of another disease, and the autopsy demonstrated the success of the surgical procedure. Aneurysms of the abdominal aorta seemed to be almost beyond the pale of surgery. Interrupted digital compression in large aneurysms occupying the pelvic vessels might be entertained. Dr. Wyeth had submitted a synopsis of 22 cases of subclavian aneurysm in which no treatment whatever was undertaken, with 18 deaths and four spontaneous cures. He had also reported 14 cases treated by rest in bed, nutritious diet, restricted fluids, and judicious medication, in which 7 were cured, 2 were improved, and 3 died; also he had reported 6 cases treated by direct pressure upon the sac, in which 4 were cured and 1 died.

Dr. Willy Meyer said the fact that Matas has been able to report at the Boston meeting of the American Medical Association no more than 34 American operations, to which number were added 6 foreign operations, made him believe that every case should be reported. He had had but one experience with the Matas operation. The patient was a boy of eleven years. He was on his summer vacation and in the woods cutting a stick with his knife; the knife slipped and struck his knee. His comrades carried him to the nearest hotel where a tourniquet was improvised, and later a doctor sutured the wound. After twelve days the boy was removed to the city. His knee was stiff. Active and passive movements were advised. The boy noticed that something gave way suddenly in the knee joint. When Dr. Meyer saw him there was a distinct aneurysm present in the popliteal space; it was the size of a fist. This was incised, the blood clots removed, and the sac cleared. The sac seemed to be the shape of a pear. In view of the fact that he had to suture obliquely he introduced a probe with a small curve into the popliteal artery; this was pressed down by an assistant, and so he was enabled to make a continuous suture. When the Esmarch bandage was removed the hemorrhage was absolutely controlled. After eight days the first dressing was removed and the patient was shown later with a perfect result, with good pulsation in the arteries below. Dr. Meyer believed that the indications for the Matas operation were going to be widened as years went by.

Dr. George E. Brewer asked Dr. Binnie what his reasons were for not using absorbable catgut. He also asked if he used any particular form of needle.

Dr. Binnie replied that he used the ordinary curved round needle. The ordinary catgut was not used in these cases, but the iodized.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

TUBERCULOSIS IN CONNECTICUT, ESPECIALLY IN RURAL CONNECTICUT.*

BY STEPHEN J. MAHER, M.D.,

NEW HAVEN, CONN.

IT seems to be the general belief nowadays that the first consumptives in Connecticut as in all New England and in all America were white men. But were they? Here are the answers of the few authorities I have been able to find.

Daniel Gookin, himself one of the earlier settlers of New England, says in his Historical Collections of the Indians of New England: "Of this disease of the consumption sundry of those Indian youths died that were bred up to school among the English. The truth is, this disease is frequent among the Indians; and sundry die of it that live not with the English. A hectick fever issuing in a consumption is a common and mortal disease among them." (Collections of the Massachusetts Historical Society, Vol. 1, page 173.)

On page 140 of the same volume, an Indian authority is given for the following statement: "Before the English came among the Indians, there were two disorders from which they most generally died, viz., the consumption and the yellow fever."

In Vol. 7 of the Massachusetts Historical Collections General Lincoln says in Observations of the Indians of North America: "Their tender lungs are greatly affected by colds which bring on consumptive habits, from which disorder, if my information is right, a large proportion of them die."

Francis, in his Life of John Eliot, the Apostle of the Indians, gives as his own opinion: "Consumption seems to have been a common malady among the New England natives."

De Forest on page 20 of his History of the Indians of Connecticut says: "The diseases of the Indians were quinsies, pleurisies, rheumatisms, quick consumption, and such others as would be naturally produced by their exposure and hardships, and by their irregular mode of life."

In a notable series of papers in the MEDICAL RECORD in August and September, 1892, on Diseases Among Indians, Dr. A. B. Holder, at one time Agency Physician at the Crow Reservation in Montana, says: "I do not believe that at any time in their history they (the Indians of North America) have been free from consumption and scrofula. In the Peabody Museum (specimen 17,-223) is a part of a vertebral column badly affected with caries-tuberculous, among prehistoric remains. (See illustration in "Orthopedic Surgery," by Bradford & Lovett, p. 2.)

"Tuberculosis is coextensive with the Indian race. The single tribe that may be said to be free from this disease, I have been unable to find after diligent search. Those who inhabit the torrid swamp of Arizona, and those in the frozen northwest territory of Canada, along the western seaboard and in the Atlantic States, all tribes suffer more or less from consumption and scrofula."

Addison in the *Canadian Journal of Medicine and Surgery* for May, 1902, tells of finding in an ossuary near Big Bay Point in Simcoe County, Ontario, several skeletons of Huron Indians that had suffered from Pott's Disease. These skeletons had been under ground for more than two centuries. He concludes that these bones are proof that not only the Indians suffered from tuberculosis before the European invasion, but also that it was a very common disease among them before the white men came.

In view of the well-known facts that the red man had no cattle, no horses, no swine, no goats, and knew not the taste of cow's milk, butter, cheese, or alcohol, it is, I think, important to remember the point that I have tried to develop in the preceding paragraphs.

After the White Man Came.—The proper registration of the causes of deaths is of very recent establishment everywhere, and there are no statistics available before 1849 for showing the proportion of deaths in Connecticut that were caused by tuberculosis. The fact that it was very prevalent during Colonial times and during the first half of the last century, is evident from letters and local histories, but figures are not to be had. Through the kindness of Dr. Joseph H. Townsend, Secretary of the State Board of Health, I am able to furnish the accompanying chart, showing as near as is possible from the records in his office, the tuberculosis death rate per 1,000, and the general death rate per 10,000, since 1849.

Of course one remarkable fact about this chart is the great decrease that it shows in the tuberculosis death rate,—somewhat irregular until 1882, but steady and impressive since that year. The average tuberculosis death rate for the past five years has been therefore 14.3 per 10,000 of population, and the death rate for all diseases has been 160 per 10,000.

Another remarkable fact about this table is that it corresponds very closely to the now famous table published last winter in Dr. H. Timbrel Bulstrode's English Governmental "Report on Sanatoria for Consumption, and Certain Other Aspects of the Tuberculosis Question." In Dr. Bulstrode's table it is shown that the phthisis death rate for England and Wales fell steadily from 27 for the 10,000 living in 1851 to 12 for the 10,000 living in 1904. And the decline in our Connecticut table is from 27 per 10,000 in 1849 to 14 per 10,000 in 1907.

Dr. Bulstrode's comment on the English table must be almost equally applicable to the Connecticut table: "The main point," he says, "which may be insisted on at this juncture, is that so far as can be gathered from the mortality returns, pulmonary

*Report made June 10, 1908, to the Connecticut State Commission for the Investigation of Tuberculosis.

tuberculosis (consumption) is tending to decrease in England and Wales, and that this decrease had been apparently taking place at a high rate prior to the belief in the communicability of the disease, to the introduction of the Public Health Act, 1875, and to the discovery of the tubercle bacillus in 1882. This fact is of great importance in relation to a proper comprehension of the tuberculosis problem.

"In so far therefore as England and Wales are concerned, it would appear that the decline in the phthisis death rate which has now been manifesting itself for over half a century, may, if continued, result ere long in the total extinction of the malady; that the malady may indeed follow the course taken by such diseases as leprosy, relapsing fever, typhus fever, malaria, etc., all of which diseases have, at least for the time being, practically disappeared from the country."

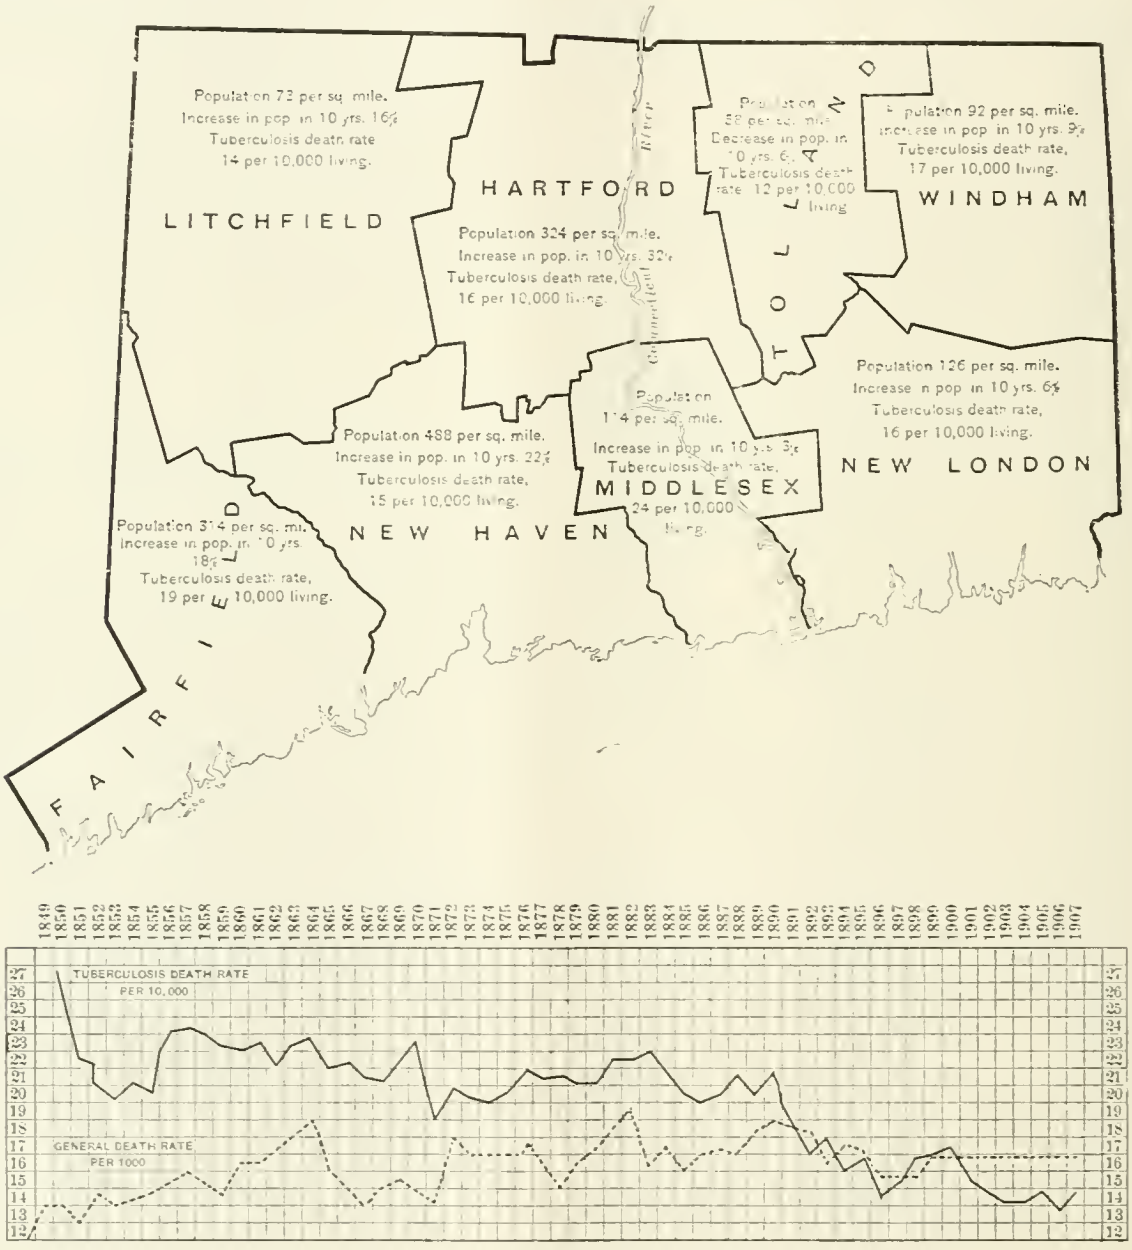
Still another interesting feature of the Connecticut table is its proof that the decrease in the tuberculosis death rate is coincident with an increase in the death rate from all causes which was only 140 per 10,000 in 1849, and was 160 per 10,000 in 1907, explainable by the incompleteness of returns in the first registration years.

Density of Population and Insanitary Environment.—We now come to the very interesting questions of the localization of these cases of tuberculosis, and the relation of the tuberculosis death rate to density of population and insanitary environment.

The State of Connecticut has an average of about 200 people to the square mile. New Haven County has 488 to the square mile; Hartford County, 324; Fairfield County, 314; New London County, 126; Middlesex County, 114; Windham County, 92; Litchfield County, 73; Tolland County, 58.

During the past ten years the population of Connecticut has increased about 20 per cent.; the population of New Haven County has increased 22 per cent.; Hartford County, 32 per cent.; Fairfield County, 18 per cent.; New London County, 6 per cent.; Middlesex County, 3 per cent.; Windham County, 9 per cent.; Litchfield County, 16 per cent., while the population of Tolland County has decreased 6 per cent.

In the statistical year, 1905-6, the death rate from tuberculosis of all kinds in the different counties was as follows: New Haven, 15 per 10,000; Hartford, 16; Fairfield, 19; New London, 16; Middlesex, 24; Windham, 17; Litchfield, 14; Tolland, 12.



Population 73 per sq. mile.
Increase in pop. in 10 yrs. 16%
Tuberculosis death rate
14 per 10,000 living.
LITCHFIELD
HARTFORD
Population 324 per sq. mile.
Increase in pop. in 10 yrs. 32%
Tuberculosis death rate,
16 per 10,000 living.
Population 58 per sq. mile.
Decrease in pop. in 10 yrs. 6%
Tuberculosis death rate 12 per 10,000 living
TOLLAND
Population 92 per sq. mile.
Increase in pop. in 10 yrs. 9%
Tuberculosis death rate,
17 per 10,000 living.
WINDHAM
Population 126 per sq. mile.
Increase in pop. in 10 yrs. 6%
Tuberculosis death rate,
16 per 10,000 living.
NEW LONDON
Population 114 per sq. mile.
Increase in pop. in 10 yrs. 3%
Tuberculosis death rate,
MIDDLESEX
24 per 10,000 living.
Population 488 per sq. mile.
Increase in pop. in 10 yrs. 22%
Tuberculosis death rate,
15 per 10,000 living.
NEW HAVEN
Population 314 per sq. mile.
Increase in pop. in 10 yrs. 18%
Tuberculosis death rate,
19 per 10,000 living.
FAIRFIELD
TUBERCULOSIS DEATH RATE
PER 10,000
GENERAL DEATH RATE
PER 1000

These figures do not represent an exceptional year. They are approximately representative of the statistics from the different counties for the past ten years as may be seen by consulting the appended tables.

The death rate from tuberculosis in the ten largest cities of this state was as follows:

City.	Population.	Tuberculosis Death Rate
New Haven	121,216	18 per 10,000
Hartford	95,822	16 " "
Bridgeport	84,274	21 " "
Waterbury	61,000	15 " "
New Britain	33,720	15 " "

Of course it can be maintained in relation to these statistics that they are not accurate; that many cases of consumption are returned as deaths from bronchitis or pneumonia or other diseases that neither suggest a family taint nor interfere with the full payment of life insurance. But there is no reason to assume that such false returns are more frequent in one county than in another. Several of my reporters from the smaller towns complain of these illegal efforts of physicians to keep the word "Tuberculosis" out of death certificates. As Dr. Bulstrode says, "It must, too, be recognized that whether reliable or not reliable, statistical records are the only tests which we possess for ascertaining the behavior of any given disease at any given time," and that, as Dr. Strauss observes on page 6 of his "La Tuberculose et son Bacille": "La statistique, malgré ses imperfections, demeure encore le meilleur élément d'enquête."

Because the conditions in the cities have been investigated by the sub-committees on Tenements and Factories, I shall confine myself in the rest of my report to a consideration of the disease among the people of the State who do not live in the larger cities. Many of the small towns of the State offer an exceedingly attractive field for the study of the subject of tuberculosis, first, because of the isolation of many of these communities, and second, because of the knowledge of local conditions possessed by keen philosophic country physicians, and third, because of the general cultivation of that useful scientific faculty, the New England conscience.

Early in April I sent the following circular letter to all the small towns of the State, addressed to resident physicians, the town clerk and the town health officer:

"I have been delegated by the Commission to prepare a report on Tuberculosis in Connecticut. The bare statistics on the subject are of course to be had at the office of the State Board of Health, but the proper interpretation of these statistics is usually possible only to one who knows local conditions. Therefore, I appeal to you for answers to the following questions and for such other help as you can give me in arriving at the truth as to the origin and spread of tuberculosis in your community.

"1. Have the cases of consumption occurred frequently in certain houses?

"2. Have these houses harbored cases of consumption only when tenanted by certain families?

"3. Have the houses in which cases of consumption occurred, been especially damp or dark, or near to unhygienic barns or coops?

"4. Have the cases of consumption been limited to one particular part of the town, or have they occurred in all parts of the town?"

The replies have been surprisingly numerous. Up to date I have heard from all but 11 of the 163 towns to which the circular was sent. Most of the men who were courteous enough to answer were satisfied with saying Yes or No to the different queries. A few of the town clerks instead of answering the questions, simply said that there was little of the disease in their towns. As a rule, the most valuable replies were from the physicians, but some of the lay officials showed a remarkably intelligent and sympathetic interest in the investigation.

To the first question, "Have the cases of consumption occurred frequently in certain houses?" —the great majority of the answers as will be seen by the table, were in the negative. Yet in the 33 affirmative replies some interesting facts were developed. Of these, sixteen only reported that the houses in which frequent cases of consumption occurred, harbored cases after a first consumptive family moved out.

Only about one-fourth of the reporters say that insanitary environment was usual in the houses in which consumption occurred, and of this one-fourth, a majority lay emphasis on a damp cellar as a common finding in the house of the consumptive.

With practical unanimity, the reporters state that the cases of consumption have occurred in all parts of the towns.

The 240 answers received from the 150 towns may be tabulated as follows:

Q. 1.—Have the cases of consumption occurred frequently in certain houses? No, 181; Yes, 33; No answer, 44.

Q. 2.—Have these houses harbored cases of consumption only when tenanted by certain families? No, 8; Yes, 16; doubtful, 1; No answer, ——.

Q. 3.—Have the houses in which cases of consumption occurred been especially damp or dark or near to unhygienic barns or coops? No, 173; Yes, 32; No answer, 48.

Q. 4.—Have the cases of consumption been limited to one part of the town, or have they occurred in all parts of the town? All parts, 202; two parts, 1; one particular part, 2; no answer, 51.

I think the Commission may be interested in a few quotations from the letters I have received in answer to my circular.

Dr. R. B. Cox of Collinsville, relates the following history: "To illustrate from my practice, a farmer and wife, apparently healthy, came from Kentucky with a family of four children, and bought a farm. As the children came to adolescence, they died of consumption until all but one are gone, and she has spent years in a sanatorium. They sold the place, but not before they had adopted two children, and moved to another. One of the adopted children is phthisical and father has active focus on lung. No family history. No signs before coming to that house. I can get no history of there having been any in the house, yet where did it come from? They are good, nice, clean, religious people."

Dr. William R. Munson of Simsbury says: "As far as my experience has qualified me to speak, there have not been two cases in the same family. The period covered by the observation is nine years, and as health officer, I covered the territory very thoroughly.

Dr. W. R. Miller, Southington, gives the following illustrations: "Three girls have died of con-

sumption in one family; four brothers alive and well. In a second family two brothers have died of consumption, two sisters alive and well. In a third family two sisters have died of consumption, one brother alive and well, but with the characteristic deformity of Pott's disease."

Dr. J. G. Adams of Canaan reports among others the following interesting case: "F. M., aged 14; no case of tuberculosis in house for years, if at any time; members of family healthy; two aunts died of tuberculosis two years ago living a half mile away, but this girl seldom saw them and never lived with them. Girl was very healthy until six months ago; since then has rapidly developed pulmonary tuberculosis. The house is very damp and unhygienic. No other cases anywhere about the country; no one has been near the girl to infect her."

Dr. W. S. Cooper, Seymour, says regarding the suggestion in question 3: "The opposite is the rule: I have had no cases of consumption but in sanitary places," while Dr. Gould A. Shelton of Shelton replies in answer to the same question: "Yes, in low localities, in dark bedrooms, and near streams and canals."

Mr. Stephen H. Mason, Town Clerk of Bristol, reports all the cases occurring in the town since January 1, 1904,—forty-three in number, and concerning them he makes the following comments: "Nearly all the cases are widely separated from each other, and no two in the same house except in two instances. I am well acquainted with the location of all the houses, and except one on Williams avenue and one on Pequabuck street, they are all high and dry."

The reporter from Broad Brook, Dr. Howard O. Allen, says in answer to question 4: "No particular part of town; though I am of the opinion that the larger number of our cases are in the near vicinity of the Connecticut River."

Dr. Lewis of Collinsville, says: "Cases have not been limited to one particular part of the town. They have been general and as frequent in the farming sections (if not more) than in the manufacturing sections."

The following interesting letter is from William Marvin, Judge of Probate and Town Clerk of Lyme: "I am deeply interested in the work of your Commission, and am glad to be of any assistance. I have examined the records of deaths in this town since October, 1896, at which time I assumed the duties of Registrar, and have taken the names of all persons who have died from tuberculosis during the eleven and one-half years which have elapsed since that date. Fourteen deaths have occurred during the period, but I shall exclude one in answering inquiries because of the fact that in that case the person came into town in the last stages of the disease, living but a few weeks.

"I am surprised to find, on looking over this list, that every death occurred within a mile of the Connecticut River, or its tributary, Eight-Mile River. This may be a mere chance, and I had never thought of the disease being at all confined to certain localities, but you will further see that nine, or nearly three-quarters of the deaths were in one very small corner as shown by the inclosed map.

"In the house marked '4' the first death occurred in June, 1897, the victim being a lady of 36, who had up to a few months before been very strong and healthy. In December, 1898, a brother died aged 29, and in May, 1903, another sister was taken at the age of thirty, after a long illness which she endeavored to overcome by out-door life here and in the West. In January, 1906, the father died at the age of about 80. The house occupied by this family has been the home of their ancestors since before the Revolution, and I am informed that no other cases have ever been known there. Although near the water, the house stands in a sunny, well-drained location.

"The house marked '2' is not as well situated but is near a large marsh, and built into a bank on the rear. The first case was that of a girl of 16, the second that of her mother, two years later, the mother having taken all the care of her daughter, and beginning to fail in health soon after her death. With the exception of two, all of the persons dying from tuberculosis since 1896 have been native Americans, and all but one have lived in this locality most of their lives. All of the homes are on a par with the average country home, and with two or three exceptions, the locations would appear to be healthful. More than half of the victims were past middle life, and only two were under twenty-five.

"In the past tuberculosis has been by no means confined to one section of the town, and a general examination of the records for fifty years back seems to show that the average death rate from this cause forty or fifty years ago was thirty to fifty per cent. greater than at present.

"I hope I have not gone into details too much, but knowing the people of my town and their condition personally, I thought these facts might be of interest.

"There have been no deaths in this town from tuberculosis for more than two years, and so far as I know, there are no clearly defined cases here at present."

Dr. George H. Wright of New Milford says that most of the cases in the neighborhood of New Milford occur among men grinding silica, and he suggests that the State find a way to do away with the dangers of the present methods of grinding, either wet or dry.

Dr. William H. Wakelee, the Town Health Officer of Southbury, in his report says: "We have in our town two houses in which the people who have occupied them for the last fifty years have died with tuberculosis.

"Taking up the matter of the first house I would say that the old residents were of New England stock, and with one exception died with said disease. About fifteen or twenty years ago, a family from Sweden, who were apparently well and strong when they arrived, lost four of the family, who died with the same disease in this house.

"The house is free from tenants at the present time, in fact has not been occupied for three or four years. The other house history shows the death of the old New England farmer, his first wife, second wife and himself, who died of consumption. Another family moved in; the father old New England stock, the mother Irish. They raised seven children, five of whom died with tuberculosis. One daughter, despondent because of her condition of health, and having been told by physicians that she would die of consumption, drowned herself. The other, a son, was drowned. Then a family from Canada, French people, moved into the house and the mother has just died with consumption. In fairness to the history I will say, when the woman came from Canada, the physician told her she had a bronchial trouble, but never told her she had tuberculosis. However, after living there a short time, she was taken with the same disease and died.

"Neither of the houses are damp or dark, nor

have barns or coops near enough to be insanitary. The cases of consumption have not been limited to any part of the town, but occurred occasionally in various sections of the town."

Dr. Stanton of Stonington reports as follows: "The percentage of deaths from this disease is next to nothing compared with thirty-five or forty years ago. The weakly ones have died off, leaving 'the survival of the fittest.'"

Dr. Walter S. Munger, Watertown, says: "In one house built by the father forty years ago, and no other family occupying it, when the youngest of the children was about twelve years old, she died with consumption; in about two years the next oldest died, and in about two years the next died,—all girls and apparently healthy until the first developed the disease. There are two older sisters still living and in fairly good health. The house is in a good situation and well cared for.

"In house No. 3, built about twenty years ago, there was a case of tuberculosis in the first family residing in it; this family moved away and another family came, and in a few years three of the second family died. When this family removed to another house another member of the family died in a few months, and then another was taken ill with the disease but was sent to the Wallingford Home and returned very much improved, and still seems to be improving. This house is on low, wet ground with damp cellar."

Mr. James R. Lanyon of Cheshire writes: "I find upon examination of the records of this town that in the last fifty years, which is as far back as the records are accurate in the matter of deaths, there were 176 deaths from tuberculosis, an average of about 3 1-2 each year. Dividing this into two periods of twenty-five years each, it shows that during the first period there were 116 deaths, a little over 4 3-5 per year; in the second period from 1882 to date, there were sixty deaths, an average of 2 2-5 per year.

"Again taking up the period from 1888 to 1898, 33 deaths, and from 1898 to 1908, 17 deaths,—which shows a remarkable decrease. I cannot find any locality where the disease has appeared for any length of time. The cases are scattered over all sections of the town, and in the majority of cases, isolated. I find that in some families there have been several deaths in one house, no cases having appeared in that locality or house either before or after the removal of that family from that particular house or locality."

Dr. Myron P. Robinson of Windsor Locks, says concerning that town: "For a manufacturing town with its mixed population, exceedingly unhygienic tenements, and no general sewer system, we have very little consumption. Our freedom from it has been ascribed to the fact that so many are employed in the paper mills which use large quantities of chloride lime; also that the chloride not only disinfects those who work in the mills, but tends to disinfect the air of the town. This would hardly seem to explain the comparative immunity from tuberculosis, for we certainly have enough other infectious and contagious diseases, except typhoid.

"In Terryville, Litchfield County, where I practised six years, we had a good many cases of consumption, and there were many houses, old, damp, and poorly lighted, where several successive families had developed tuberculosis, often two, three, and even five members of the same family dying one after the other.

"I cannot say that unhygienic barns or coops were a factor, but dampness, filth, and failure to paint and whitewash, after the house had been infected, were nearly always factors."

Dr. William E. Reynolds says that in Woodbury the cases have occurred "In the valley, and on the mountain top; in all parts of the town."

Dr. C. E. Brayton of Stonington reports: "Many of the houses are very old, many over the century mark, and more from fifty to ninety years of age. In many, no doubt, there has been more than one case of tuberculosis, but I do not recall any marked case.

"Regarding this place, we have had considerable tuberculosis during the thirty-five years of my practice, but I believe not as much as in many towns of like size. It has been among all classes, rich and poor, native and foreign born, and, I must confess, with a good many cases in the same family.

"In years past it is of record that whole families like the Y.'s, a family of six, and the H.'s, a family of seven, were taken one by one, until all are gone, or maybe one left to grow old."

Mr. R. C. Usher, Registrar of Vital Statistics in Plainville, gives the following succinct data: "In one house, same family, six deaths; one house same family, four deaths; three houses, same family, three deaths; one family three deaths in two houses; one family four deaths in three houses; nine families two deaths each in nine houses."

He says that 125 cases have been reported since they organized as a town in 1869—forty-four cases in sixteen families, and eighty-one cases in as many families, scattered.

The following history is from a town in Litchfield County:

"James and Margaret, now each ninety years old, were the parents of seven children, five girls and two boys. The children all died of tuberculosis and the parents still live. The last child died four years ago last fall. All were born and raised on the farm, and all were well developed and well nourished. All but two of them died on the farm. The farmhouse was low studded, a short roof on one side and a long roof on the other side reaching to the ground. The barn was fifty feet away. In it were usually kept twelve to fifteen cows and horses,—no goats or sheep. This barn was unhealthy and located between three swamps, which were an eighth, a tenth, and a sixth of a mile distant. Most of the children assisted in the milking of the cows. The milk was used on the place and made into butter and cheese. The girls usually left home about sixteen years of age to work in hotels and families as servants, and usually returned home sick, where they lasted from six months to four years."

Conclusions.—1. Tuberculosis was a disease of the Indians of Connecticut before the white man came.

2. Human tuberculosis has occurred in all parts of rural Connecticut,—highland and lowland and plain.

3. There is considerable evidence to show that in rural Connecticut human tuberculosis occurs most frequently in badly drained districts, and in houses with damp cellars.

4. The reports received do not support the view that in rural Connecticut cases of consumption occur frequently in close proximity to insanitary barns or coops.

5. While the preponderance of testimony is that in rural Connecticut only a minority of cases of consumption have been followed by other cases in the same house or the same family, the evidence in favor of the hypothesis of "consumption houses"

and "consumptive families" is often very striking and is deserving of careful consideration.

6. The density of the population of the counties of Connecticut bears no relation to the tuberculosis death rate of said counties.

7. There has been a very marked decline in the tuberculosis death rate for the past fifty years, and this decline was as steep but not as regular before the discovery of the turbercle bacillus as it has been since.

212 Orange Street.

AUTOCHTHONOUS URETHRAL CALCULI; REPORT OF A CASE.

By HARRY ATWOOD FOWLER, M.D.,

WASHINGTON, D.C.

Cases of urethral calculus, while not very rare, are yet relatively uncommon. Probably the number of such cases is much greater than is indicated by the literature, as only those which present unusual and interesting features are generally reported. When we consider the relative frequency of renal and vesical calculi and the frequent occurrence of pathological and physiological narrowing of the urethra, it is not remarkable that a stone should be frequently found lodged behind such obstructions.

The great majority of cases belong to this group of secondary urethral calculi; that is, the calculus is formed at a higher level in the urinary tract, kidney, or bladder, and passes into the urethra where its further progress is arrested by some obstruction, either a normal or an abnormal narrowing of the canal. Owing to the fact that the caliber of the urethra is not uniform throughout, there are certain points at which a calculus which has escaped into the urethra from the bladder is most likely to lodge. Thus they are most often found in the fossa navicularis, in the bulbous, membranous, or prostatic portions of the urethra. In those cases where the calculus is associated with a stricture, the location of the stricture will determine the position of the calculus.

We can divide the cases of secondary urethral calculi into several groups or classes, depending upon the fate of the calculus or the changes produced by it after reaching the urethra. In some cases, as soon as the calculus escapes into the urethra from the bladder, it produces such violent symptoms as to make its immediate removal imperative. Not infrequently the presence of a stone in the bladder may not have been suspected, it may not have given rise to any symptoms whatever, or produced only moderate discomfort, when it suddenly slips into the urethra and produces such extreme pain and distress that its early removal is demanded. In other cases the urethra is more tolerant of the foreign body, and the calculus may remain in the canal for long periods without undergoing further change itself or producing any marked change in the surrounding tissues.

In a third group of cases, the calculus continues to grow after reaching the urethra, by the deposition of new material on its surface. Such stones remain in the urethra sometimes for years, increasing slowly in size, until they attain relatively enormous dimensions and produce a marked dilatation of the urethra. Cases of this kind are recorded in which the calculus, gradually increasing in size, filled almost the entire anterior urethra. Such a case is briefly reported by Fisher. This patient, forty-nine years old, a Western cattleman, had all his life ridden the range. At ten years of age his urethra was obstructed by a "growth." Several ineffectual attempts were made to pass a catheter. A fistula formed behind the "growth," and through this practically all the urine was voided. The pain on riding in the saddle was almost unbearable. At the operation a stone was removed from the anterior urethra which extended from the bulb to the glans. It measured two and five-eighths inches and five and one-fourth inches in diameter, seven and three-fourths inches and thirteen inches in circumference, and weighed nineteen and one-half ounces. This case is interesting, not only on account of the large size of the calculus, but as illustrating how long a patient will sometimes suffer a stone to remain in the urethra and continue to lead an active life.

In still another group of cases, the calculus, which at first lodges in the urethra and obstructs the lumen, slowly migrates into the periurethral tissues, and may eventually come to lie entirely outside the lumen of the urethra. The cavity so formed may communicate with the urethra by a wide or narrow mouth, or it may become completely shut off, and at operation the calculus is removed from a paraurethral pouch without opening into the urethral canal. This migration of the calculus probably takes place somewhat as follows: largely as a result of pressure by the calculus, the wall of the urethra gradually gives way, and a pouch is formed. This increases slowly with the increase in size of the calculus, the distention probably being aided by the pressure of urine at each urination. When a pouching of the urethra occurs, its further development is not unlike that which occurs in esophageal diverticula. The calculus sinks deeper and deeper into the periurethral tissues, the connection with the lumen of the urethra becomes smaller and smaller, until finally the opening may be entirely closed, and the stone then lies outside the canal. Cases illustrating the various stages in the migration of a urethral calculus from the urethra into a paraurethral pouch have been reported.

Fig. 1.—Lateral view of calculus. Natural size. Vesical end toward the left. The groove made by the external sphincter is seen on the upper (anterior) surface. The dark areas are due to staining with permanganate of potash after removal. The surface on removal was perfectly smooth and ashy gray in color. Weight, 106 grams.

Thus we can divide the cases of secondary urethral calculi into at least four groups according to the ultimate fate of the calculus, or the changes which it undergoes after reaching the urethra. In all of these cases, the calculus is formed at a higher level in the urinary tract, and only secondarily reaches the urethra.

In a smaller and more interesting group of cases, the calculus develops *primarily* within the urethra. These are much less frequently observed. There are, in fact, writers who hold that a calculus

never develops primarily in the urethra. Indeed, widely different views have been expressed as to the origin of urethral calculi. Legueu, for example, has said that in every case the calculus is formed in the kidney or bladder, and only secondarily becomes urethral. Gräfe, on the other hand, considers that

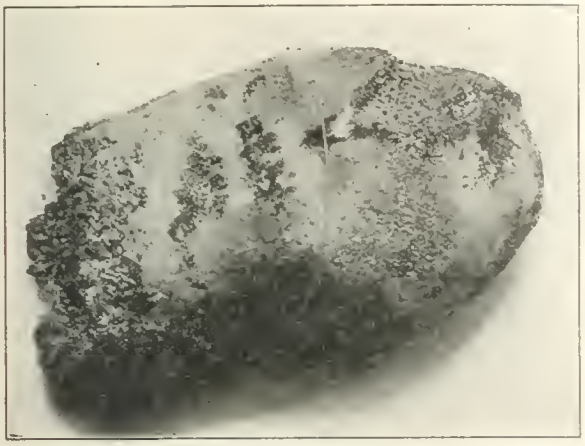

Fig. 2.—Lower (posterior) surface. Vesical end to the left is very rough, due to projecting crystals of phosphate of lime. Remainder of calculus smooth. The rough area at the upper right corner is due to abrasion with forceps during removal.

all calculi which have remained in the urethra for any length of time, are formed primarily within the urethra, since any calculus which is arrested in its passage through the urethra gives rise to such urgent symptoms as to demand its immediate removal. The truth undoubtedly lies between these two extremes; while in the mapority of cases the calculus is formed in the kidney or bladder, and lodges in the urethra, there are undoubted cases reported by competent observers, in which the calculus is of primary urethral origin.

That a calculus may form in the urethra is abundantly proven by clinical experience. One not infrequently finds phosphatic incrustations along fistulous tracts and the walls of abscess cavities communicating with the urethra. The remarkable case of Dupraz, quoted by Suter, offers convincing proof that primary deposition of salts may occur in the urethra. A man treated himself for urethritis for eight months with injections of a "water" recommended by a comrade. This "water" was carbonated. The symptoms were relieved, but a stricture developed, and examination showed that the entire anterior urethra was lined by an incrustation of carbonates. Friedländer, also quoted by Suter, observed a patient with stricture who had incrustations of phosphates in the urethra which were removed in splinters with a pair of forceps.

The conditions which are essential to the formation of a calculus in any part of the urinary tract are present in the urethra, associated with a variety of pathological conditions, such, for example, as stricture, inflammation of the glands with the formation of minute abscesses, diverticula of the urethra, and in fact in any case of solution of continuity of the uethral wall, such as occurs in incised wounds, injury, rupture, etc. Any obstruction to the escape of urine tends to produce a dilatation of the urethra behind this point, and favors the retention of urine. Such stagnant urine readily undergoes alkaline decomposition, which is an important factor in hastening the precipitation of the urinary salts, particularly the phosphates. The organic material, so essential to the formation of a calculus in any part of the urinary tract, is abundantly furnished by the desquamated epithelium, pus, blood, and mucus. Unquestionably the most important factor is obstruction with resulting retention.

Primary urethral calculi develop either (1) in the lumen, or (2) in a diverticulum of the urethra. When in the lumen, there is probably always some change in the urethral wall, either with or without resulting stenosis and dilatation behind the obstruction. Bazy has raised the question whether or not a calculus can form in a healthy urethra. He states that while this is improbable, yet a personal observation seems to favor this view. That a calculus sometimes develops at the site of a lithotomy wound has long been known. The symptoms develop, in some cases, only after an interval of years after the determining cause. Thus, following trauma, cases have been recorded where an interval of 17, 20, 26, and even 31 years elapsed before the appearance of symptoms of stone.

When a calculus, either primary or secondary, continues to grow in the lumen of the urethra, marked dilatation of the canal may result. Cases of unusual dilatation of the urethra have been reported by Kurbatow, Tesjakow, Rörig, and Fisher. In our own case, the urethra was enormously dilated.

In Kurbatow's patient, aged forty-three years, symptoms of stone had been present for six years. Two years before, a urethral fistula had formed, and a small stone escaped. A stone was felt by a sound in the urethra and by a probe in the fistula. At operation two stones were removed from the urethra, one measured 9 by 9.5 cm., and weighed, when moist, 390 grams; the second weighed 11.25 grams.

Rörig's patient, aged forty-five years, had suffered with dysuria and "paralysis of the sphincter" since his nineteenth year. A swelling in the perineum, extending from the scrotum backward, was felt externally and through the rectum. A stone 8 cm. long, 6 cm. in its anterior and 3 cm. in its posterior diameter, and 17 and 23 cm. in circumference was removed, weighing 250 grams. It lay in the bulbous, membranous, and prostatic portions of the urethra. In removing the stone the rectum was injured and the patient died on the twentieth day.

Tesjakow's patient, eighteen years of age, com-

Fig. 3.—Cut surface of the same, slightly enlarged. The nucleus lies in the center of the calculus in the same plane as the groove made by the external sphincter. The arrangement into indistinct concentric layers, especially in the outer portions, can be made out.

plained of pain on urination. He had passed several stones through a scrotal fistula. A stone was felt through this fistula and by a probe in the urethra, 2 cm. from the meatus. Twenty stones were found in the urethra, the largest weighing 67 grams. The total weight was 106 grams. The dilatation

of the urethra extended from the membranous urethra to a point 2 cm. from the meatus. Fisher's case has been cited above.

The history of our own case is as follows: R. W., colored, aged thirty-three years, was admitted to the hospital complaining of incontinence of urine and pain in the perineum. Ten years ago, while working on an elevator in Chicago, he fell down a shaft, a distance of 95 feet, sustaining a fracture of the pelvis. Following the accident, he was unable to void urine and a catheter could not be passed to the bladder. A perineal section was done at once. The patient remained in the hospital three months, at the end of which time he was discharged perfectly well. One year afterward an abscess developed in the left testicle which was removed. He now began to suffer with frequent urination, accompanied by severe cutting pain in the perineum, and associated with the escape of pus and blood from the meatus and in the urine. During the next two years he was treated at one of the local dispensaries. He was told that his trouble was evidently from a stone, but nothing was ever found on repeated soundings. Operation was advised and refused. He then returned to his home in Virginia, where he has since been working on a farm. During the past six years he has not consulted a physician, and has taken no treatment save large quantities of water and patent medicines. During this time he has worn a rubber urinal constantly. While moving about, if the urine was not escaping constantly, he suffered great pain in the urethra. To keep the urine flowing freely he drank "gallons of water every day." When sitting quietly he could hold his water for fifteen minutes. Finally, the suffering became so intense that he sought relief, and entered Freedmen's Hospital in February, 1907. He has complete loss of sexual power which came on two years after the accident.

Healthy young colored man, presents the facies of a constant sufferer. Examination of chest and abdomen negative. There is double inguinal hernia which, he states, has developed since his present trouble began. He is wearing a rubber urinal and there is constant dribbling of urine when standing. A distinct depression can be felt in the pubic arch in the midline, as though the bone had been driven downwards and backwards by a blow delivered from above and in front.

In the perineum is a rounded swelling along the course of the urethra, extending from the scrotal margin behind, backward nearly to the anus. This swelling is very prominent, rounded from side to side; the examining finger can be pushed up into a deep sulcus between the mass and the ramus of the ischium on either side. The mass is very hard, tender, and immovable, as though attached to the bone above.

Rectal examination is very painful; the introduction of the finger is followed by the escape of a quantity of pus and urine from the meatus. A rounded, very hard mass can be felt in the position of the prostate, regular in outline, and very tender. The bladder wall is easily reached above and appears normal. The region of the vesicles is free.

Urethra.—A small silk catheter passed easily a distance of 7 cm. where an obstruction was met against which the catheter grated. A small silver catheter was then used and the distinct, characteristic click of a stone was obtained. The silk catheter was again used and passed to the bladder. The urine was light in color, turbid, very foul smelling, and contained pus and bacilli in abundance.

Operation.—The membranous urethra was exposed by using the same incision as for perineal prostatectomy. We seemed to be behind the most prominent part of the mass, which extended forward in the bulbous urethra. The incision into the urethra was made through the bulb and at once the large, rounded, smooth, posterior surface of the stone was brought into view. In order to expose the anterior end of the calculus, the urethra had to be freely opened as far as the scrotal margin. Lateral incisions through the dilated bulb were necessary to free this portion of the calculus, and permit us to get around it and dislodge it from its bed. The incision was carried backward through the membranous urethra. It was impossible to tell, at this point, how far the calculus extended posteriorly, or to ascertain its shape or size. It was firmly fixed in position, wedged in between the rami of the ischium. Wishing to remove it entire, the outer end was grasped by a pair of stone forceps, by working one blade of the forceps between the calculus and the anterior wall of the urethra. By firm, steady traction with both hands, wrenching carefully from side to side, the stone was finally dislodged without injuring the soft parts, and removed entire. After the removal of the stone, the interior of the bladder could be inspected through the dilated membranous and prostatic urethra, which formed a circular opening approximately 5 cm. in diameter. The incisions in the bulbous urethra were sutured and the wound was packed lightly with iodoform gauze. No drainage tube was used. There was no attempt made to reduce the size of the greatly dilated urethra. The wound healed promptly.

The shape and size of the calculus are shown in the accompanying illustrations from photographs. When removed, the surface was smooth, except the vesical end, which was markedly rough and jagged The color is a pale ash gray. The measurements are as follows: length, 7.4 cm.; width, vesical end, 3.5 cm., urethral end, 4.7 cm.; circumference, 19.8 cm., vesical end, 14.2 cm., urethral end, 13.7 cm. When perfectly dry the stone weighs 106 grams. It is composed chiefly of calcium phosphate with a small amount of ammoniomagnesium phosphate. There is no uric acid, urates, or oxalate of lime.

The structure of the cut surface is well shown in the illustration. It will be seen in this view that the nucleus lies in the same horizontal plane as the groove made by the external sphincter muscle. That is to say, the nucleus of the calculus was formed in the membranous urethra, and it lies in the center of the stone. Growth occurred in both directions, toward the bladder and toward the anterior urethra. It is stated that in urethral calculi the nucleus will generally be found in the outer end, and that growth takes place chiefly toward the bladder. It is apparent that such was not the case in our specimen.

As to the origin of the calculus, it is evident that it is of primary urethral formation. We assume this from the history of the case, and the structure and composition of the calculus. There was no history of urinary trouble previous to the accident. At that time there was an injury to the urethra, making it necessary to open the bladder through the perineum. Following the injury, there was no urinary disturbance for a period of a year. Then began those symptoms which continued for nine years and finally compelled the patient to seek relief. The abscess of the testicle, which was removed, was evidently associated with the urethral condition and due to a descending infection. At no time did the symptoms become suddenly worse or change in

character, as when a stone enters the urethra from the bladder. No stricture of the urethra in front of the calculus was found at the operation. It is evident, therefore, that the formation of the calculus was intraurethral, and was associated with or depended upon, injury of the urethra. The extent and nature of this injury we do not know, but it must have been severe as the patient could not void urine and it was impossible to reach the bladder with a catheter. We have, then, in this case an example of trauma of the urethra followed by the development of a calculus.

The size of the stone is noteworthy. A relatively small number of similar cases have been reported in which the calculus was as large or larger. In recent literature only four cases similar to ours are found in which the stone was larger. In three of these the stone was removed by operation; two patients recovered and one died twenty days afterward from an injury to the rectum during the operation. In the fourth case the stone passed spontaneously through a fistula.

Our specimen belongs to the large group of phosphate of lime calculi. Triple phosphates are present only as an impurity. Calculi composed entirely or chiefly of triple phosphates are exceedingly rare. Suter reports one such case.

Calculi formed in diverticula of the urethra sometimes attain enormous size. The largest urethral calculus recorded belongs to this group. This case was reported by Bourdillat, the weight of the calculus being 1,450 grams! A calculus may form in a diverticulum and, vice versa, a diverticulum may result from the growth of a calculus. It is sometimes difficult to say which is primary, the calculus or the diverticulum. Urethral diverticula are either (1) true or (2) false. A true diverticulum is one in which all the layers of the wall of the urethra are present. While it is easy, theoretically, to distinguish between these two, in practice it is often difficult, and sometimes impossible. The inner lining of a true diverticulum may be completely destroyed by a stone or inflammation, and the wall changed into fibrous tissue indistinguishable from that of a false diverticulum. It is claimed, furthermore, that a false diverticulum may be lined by epithelium which grows in from the adjacent epithelial lining of the urethra.

True diverticula may be either (1) congenital or (2) acquired. Congenital diverticula are very rare. Watts, in 1907, was able to collect but sixteen cases, to which he added one. They occur most commonly in children; the pouch is formed, usually, in the anterior urethra. In adults it is extremely difficult to say whether a diverticulum is congenital or not. The occurrence of stones in this form is very unusual. Not more than three or four cases have been reported.

Acquired diverticula of the urethra are more common. They arise from either (1) dilatation of the urethra by a stone or stricture or (2) perforation of the urethra from injury or the rupture of a cyst or an abscess. As distinguished from the congenital form, they occur most commonly in adults, and the membranous urethra is the favorite site, although they may occur at any point.

The occurrence of stone in acquired diverticula is not at all common. The number of cases reported does not exceed twenty-five.

There is at present no generally adopted system of nomenclature, by which one can conveniently indicate to which class any particular case of urethral calculus belongs. Indeed, there is no uniformity of opinion among writers on this subject, as to what cases should properly be included under the term "urethral" calculus. The term is used in a widely different sense by various writers. As generally employed, it was made to include all cases in which a calculus occurs in the urethra, without reference to its origin. In his paper in 1896 Lieblein contends that this use of the term is too broad. He holds that only those cases should be included where the calculus forms primarily within the urethra, or undergoes further growth by the deposition of new layers on the surface after reaching the urethra. In this restricted use of the term the number of cases would be greatly reduced. In a review of the literature Lieblein could find only fifty-four out of over two hundred cases which could be properly admitted in the narrow sense in which he used the term. This view has been adopted by others, notably by Kaufman and Urstadt.

In this restricted use of the term we must exclude those cases where a calculus forms in the kidney or bladder, lodges in the urethra, and there produces such acute symptoms as to demand operative interference for its removal. It may be that such a stone, while in the kidney or bladder, gave no discomfort calling attention to its presence. Only after reaching the urethra did it make its presence felt and, as a stone in the urethra, produced the symptoms which led to its detection and removal. How are we to designate such a calculus? We term any calculus, occurring in the bladder and producing symptoms, a vesical calculus, without reference to its origin, be it of primary formation in the bladder, or a kidney stone which has passed into the bladder. In the same way it would seem that any calculus found in the urethra should be called a urethral calculus, whether primary or secondary.

We recognize the necessity of some means of properly designating these cases. We should be able to differentiate, by some appropriate term, a calculus which has its origin in the urethra from one which forms at a higher level and becomes lodged in the urethra, with or without undergoing further development.

Suter has proposed the following system of nomenclature which, while not novel, appears to us to be very satisfactory. All calculi occuring in the urethra are to be designated as urethral calculi, whether primary or not. The term indicates where the calculus is found, without reference to its origin. To indicate its origin, we may employ modifying terms, indicating whether the stone arises within the urethra itself, or wholly, or in part outside. The terms proposed are autochthonous, heterochthonous, and amphichthonous. Autochthonous urethral calculi are formed in the urethra; heterochthonous urethral calculi are formed wholly outside the urethra; amphichthonous urethral calculi have their origin outside the urethra, but increase in size, by the deposition of new layers, after reaching the urethra. If we know the origin of the calculus in any given case, as for example, a vesical calculus which slips into and is arrested in the urethra, without undergoing any increase in size, then it may be called a vesicourethral calculus. If such a stone continues to grow after reaching the urethra, then we may call it a vesicourethral-urethral calculus, etc. The three main groups are sufficiently described by the modifying terms autochthonous, heterochthonous, and amphichthonous. It is apparent that those cases belonging to the second group, the heterochthonous urethral calculi, cannot be included under the term "urethral" calculi in the restricted meaning of the term employed by Lieblein. The suggestion of Suter seems to us very satisfactory in that it permits

us to readily and accurately classify all cases of this kind, and we can indicate by the use of a single modifying term whether the calculus is of primary urethral origin, or reached this point secondarily.

The symptoms produced by a urethral calculus depend upon several factors, such, for example, as the size and shape of the calculus; its position in the urethra; its etiology, whether primary or secondary; the presence of infection, etc. Relatively large calculi may pass the urethra when there is no pathological obstruction present. If the stone is rough and angular the pain is severe, and hemorrhage may be profuse. On the other hand, a very small calculus may lodge behind a tight stricture and cause most distressing and alarming symptoms. (McGuire's case, calculus the size of a buckshot.) In one of my own cases, operated upon during the past year, a small stone impacted behind a tight stricture of the membranous urethra, caused most intense suffering. A brief report is given as this case illustrates not only the severe symptoms sometimes produced by such small stones, but also the difficulty sometimes experienced in detecting and removing such a stone.

G. B., aged sixty-two years, was seen in consultation in June, 1906. He complained of frequent and painful urination. He had gonorrhea at eighteen years of age which lasted five or six months. The discharge has recurred three times. He has had internal urethrotomy performed three times for stricture, each time followed by profuse hemorrhage. He has taken chloroform eleven times to have the stricture dilated. Two years ago, following a debauch of several days' duration, he had marked hematuria lasting twenty-four hours. Once since he has passed a considerable number of blood clots. There has never been any pain in the region of either kidney or along the ureters. The only urinary trouble, aside from the hematuria, has been the difficulty of voiding due to the stricture.

Present Illness.—In February, 1906, following a sudden violent exertion, he noticed something slip into the urethra. He then first noticed that he passed his urine in a smaller stream than usual and at frequent intervals. And after urinating he had severe pain, sharp and cutting in character, located in the root of the penis and radiating along the left side of the urethra to the glans. Just previous to this he had passed his urine much more freely, at normal intervals, and without pain. His symptoms became more marked, the suffering with each urination was intense, and the pain in the urethra on walking about became so great that he was compelled to take to his bed.

When first seen, he was emaciated and extremely nervous. In urinating he assumed a peculiar posture. He would squat down with the thighs strongly flexed on the abdomen and the knees bent. In this position he would wait for a considerable time for the urine to flow. As the stream started, he would raise himself by straightening the legs, keeping the body bent forward, and swaying backward and forward by rising himself on his tiptoes. The urine was voided in a fine stream. The act was followed by severe, cutting pain along the left side of the urethra, extending from the root of the penis to the glans.

The urine was turbid, very foul smelling, alkaline, sp. gr. 1010, albumin present. There were no casts, few pus cells, red blood cells, abundant crystals of triple phosphates, and bacteria. The patient was so nervous that no local examination, not even rectal was possible. Suspecting a urethral calculus associated with a stricture, the patient was sent to the hospital for examination and operation. Under an anesthetic we found a stricture, 5 cm. from the meatus, which was readily dilated. In the membranous urethra there was a second very tight stricture which permitted only a filiform to pass. This was dilated by using a filiform and a Le Fort follower until a No. 19 F. sound could be passed easily to the bladder. No stone could be felt in the bladder and nothing was felt at first in the urethra. Withdrawing and introducing the sound repeatedly and searching the urethra carefully, a stone was finally detected lying behind the stricture. Opening the urethra in the perineum a small oval calculus was found lying in a pouch behind a tight stricture of the membranous urethra. After dilating the stricture further some difficulty was experienced in grasping the calculus. It was finally pushed back into the bladder where it was readily grasped and removed. The patient made a good recovery. He is now perfectly well, urinates at normal intervals and without pain. His urethra admits a Kollman dilator which can be opened to No. 36 F. with ease.

The calculus is egg shaped, light cream in color, with a smooth, polished surface, and measures 1.3 by 0.9 cm. It is composed of pure phosphate of lime.

In children the sudden blocking of the urethra by a stone causes most violent symptoms. Acute retention often results. This is rare in adults, except in association with stricture. There is more often in adults a sudden stoppage of the steam, followed by a diminution in its size, with dribbling of urine. Pain is always a prominent symptom. It is usually localized in the urethra, either at the site of the calculus, or referred to the anterior urethra and the glans penis. Cases in which the reflex pain was referred to the back, abdomen, and pelvis have been reported. Dysuria is usually marked. When the calculus is lodged in the prostatic or membranous urethra, or when associated with a tight stricture, incontinence of urine is a distressing symptom.

These symptoms are all due to the presence of a foreign body in the urethra, and the mechanical obstruction to urination produced by it. There is usually only slight hematuria due to the fact that the stone is fixed and immovable. When infection occurs the picture changes completely. The symptoms become aggravated, the pain is greatly increased, and suppuration sooner or later occurs with abscess formation and fistula. A patient will tolerate a calculus in the urethra, sometimes for years, being able to endure the discomfort to which it gives rise as a result of the mechanical irritation, but if infection occurs the symptoms become so severe as usually to require active interference.

As a rule autochthonous urethral calculi produce much less acute symptoms than the secondary variety. The urethra is apparently more tolerant. Exceptionally a patient may carry a very large stone in the urethra for years without suffering any inconvenience and without a suspicion of its presence. Such a case is reported by Wolf. A man, aged fifty years, died of cellulitis of the leg, cirrhosis of the liver, etc. At the post mortem a calculus was found in the urethra weighing 23.62 grams and measuring 4.6 by 3.3 cm., and lying 5 cm. behind the meatus. The urethra over the calculus was crescentic, the latter lay in a pouch composed of all the layers of the urethra. This diverticulum is supposed to have been congenital, and contained, besides the large calculus, about 130 millet seed calculi. There had been no symptoms during life referable to the

urethra. In the case recorded by Jawitzki, a stone was present in the urethra for thirty-five years, during which time the patient had led an active life.

The diagnosis is usually simple; sometimes it is very difficult. If the stone lies in the lumen of the urethra, it is readily detected by a metal instrument, and a positive diagnosis made. When a fistula has formed the stone, if present, can often be felt by a probe introduced into the fistula. In those cases where the calculus lies in a diverticulum, the diagnosis is not so readily made. Urethral instrumentation in these cases may be negative. A tumor in the line of the urethra can usually be palpated externally, it may be hard and very tender, but unless crepitation is elicited, which is rare, one cannot always differentiate between a stone and a mass of scar tissue so often found in the scrotal and perineal urethra surrounding an old fistulous tract. In some cases the true nature of this swelling is determined only by incision. In an interesting case reported by Chevassu, three urethral calculi were detected in a pouch of the urethra by the *x*-rays. This sac held 40 c.c. and was distended with each urination, the urine dribbling away after the act.

When a small calculus is impacted behind a tight stricture its detection is difficult; it may be overlooked altogether. In our own case, recorded above, it was only by repeated and careful search of the urethra after the stricture had been dilated that the stone was felt. In Recoviceano's case there was a calculus in the prostatic urethra associated with a stricture. Examination with a sound did not reveal a calculus. An internal urethrotomy was performed without a suspicion of the presence of a calculus. Three weeks later septic symptoms appeared. Exploration of the urethra was again negative for stone. A hard mass was found in the perineum. An opening was made and a calculus extracted.

Treatment.—A small calculus in the penile urethra can sometimes be removed with the urethral forceps. In one such case, where the stone was freely movable behind a narrow point of the canal, I was able to fix the calculus by pressure on the urethra behind it, and remove it with the urethral forceps. Great care must be taken to avoid injury to the urethral wall, particularly in the presence of infection. In one such case reported gangreme and extensive sloughing of the urethra followed the removal of a small calculus impacted in the penile urethra. Attempts to crush the stone by pressure from without should never be made. If the stone cannot be readily removed by the forceps, it is safer to do an external perineal urethrotomy and remove the stone by displacing it backward. If this does not succeed one should then cut down on the stone, remove it, dilate the urethra, and suture, leaving the perineal wound open for drainage until the wound in the penile urethra has completely healed. For all large stones in the deeper urethra external perineal urethrotomy is the operation of choice. It will rarely be necessary to open the bladder above the pubes. In some cases of a small stone in the prostatic urethra it is possible to push it back into the bladder and remove it with a lithotrite.

In a large proportion of cases, nearly one-third, multiple calculi are present. In Grobe's case 183 calculi were removed. Karajew removed 85 stones from a sac behind the prostate and during convalescence 415 more were passed. Silthorpe removed 80 stones from a pouch behind a stricture of the scrotal urethra. These were palpable externally.

In some cases of multiple calculi of the urethra the separate stones present facets by which they articulate with each other. In the most common variety of faciculated calculi, the whole mass is lozenge-shaped, conforming to the shape of the urethra. The individual, disc-like pieces articulate with each other by flat surfaces. In other forms the individual calculi may present very irregular, bizarre outlines, the whole forming a more or less spherical mass. Such a case is described and figured by Desnos.

The largest urethral calculus I have found reported in recent literature is the one recorded by Fisher, weighing nineteen and a half ounces. This case is unusually interesting in that the calculus was limited to the anterior urethra. The calculus in Kurbatow's case weighed 390 grams, and in Rörig's, 250 grams. Kapsammer removed a calculus, weighing 162 grams, from a vaginal sac situated between the prostate and rectum. Naguera reports a case of a urethral calculus, weighing 130 grams and measuring 14 cm. by 8 cm., which was passed spontaneously through a fistula.

The great majority of urethral calculi are composed of phosphates, the phosphate of lime predominating. Ammoniomagnesium phosphate is usually present as an impurity, or it may form a large part of the calculus. In only one case reported was this substance present in a pure state. Heterochthonous urethral calculi may be composed of uric acid, urates, oxalate of lime, cystin, etc. In the amphichthonous forms these substances may form the nucleus while the outer layers are composed of phosphates. According to Kaufman, all urethral calculi composed of uric acid, urates, oxalate of lime, and cystin are of secondary urethral origin. Lieblein, however, reports a case of a primary urethral calculus composed of uric acid. Hence we must modify this view of Kaufman, and admit the possibility of the primary deposition of these substances, at least uric acid, in the urethra.

THE ESOPHAGOSCOPE AS A DIAGNOSTIC AND THERAPEUTIC AID IN ESOPHAGEAL OBSTRUCTION—REPORT OF CASES.*

By JESSE S. MYER, M.D.,

ST. LOUIS, MO.

LECTURER IN MEDICINE, MEDICAL DEPARTMENT, WASHINGTON UNIVERSITY

PRACTICALLY all diseases of the esophagus manifest themselves through an interference with the peristaltic waves. Dysphagia is the first and chief symptom of esophageal obstruction, regardless of the character of the pathological lesion. There is, therefore, no class of cases which gives both physician and patient greater anxiety than do obstructions of the esophagus, because in their incipiency, at least, there is always grave doubt as to the malignancy of the affection. It is not so important from a therapeutic standpoint that the presence of carcinoma should be determined early, for there can be no more unfavorable location for surgical interference than the lower two-thirds of the esophagus, but it is important with reference to both prognosis and treatment, that one should be able to exclude carcinoma as soon as possible.

In view of the paucity of symptoms in esophageal diseases in general, and the prominence of one symptom in practically all of these diseases, a definite diagnosis based upon symptomatology alone is difficult—in fact, often impossible. The location of the

*Read before the St. Louis Society of Internal Medicine, April 15, 1908.

esophagus renders the physical examination practically resultless, and until recently esophageal sounds and the *x*-ray were practically the only appliances which were of aid. The esophagus, therefore, is the organ par excellence in which the sense of sight could prove, and has proven, of inestimable value. The use of the esophagoscope then is the logical method for determining at the earliest moment the true character of esophageal obstructions. Only in the last decade, however, may it be said to have found its own as a diagnostic and therapeutic aid.

Prior to 1896 comparatively little had been done in the direct examination of the esophagus through the aid of the eye. Diagnoses were based largely upon the symptomatology and the use of esophageal sounds, and, while these methods are of great value, there is scant doubt that esophagoscopy will become quite as indispensable in the study of diseases of the esophagus as is the proctoscope in diseases of the rectum, and the cystoscope in diseases of the bladder.

The first practical work was done by v. Mikulicz in 1881, with a perfectly straight tube, though the way had already been paved by Stoerk (1866), Waldenburg (1870), and McKenzie (1880). These authors employed devices with laryngeal mirrors attached, and thus obtained a reflected image of a portion of the esophagus. v. Mikulicz employed a long, straight tube—long enough, in fact, to be passed into the stomach, with the light at the distal end. His researches along this line were of the same value that always characterized his work. He added much to our knowledge of both the physiology and pathology of the esophagus. His instrument, however, was used almost entirely for purposes of observation, being of little value from a therapeutic standpoint, because of the position of the light within the tube.

Von Hacker, in 1889, began his work, using the instrument of Mikulicz with the light reflected into the tube by means of an incandescent lamp at the proximal end. This was the beginning of the method used at the present time. He, too, was able to make most valuable contributions to our knowledge on this subject. Rosenheim, in 1896, added his ingenuity to that of his predecessors in the work, and succeeded in perfecting an instrumentarium which has been improved upon but little up to the present time. He used the tubes of various lengths, just as they are used at present, with a hard rubber obturator, having a soft rubber tip instead of bougies, such as are employed by Killian and others in their work. Kelling, Kraus, Gottstein, Gluecksman, Killian, v. Schroeder, and Jackson of this country, have all added their modifications, many of which are of value, but the principle of the esophagoscope has remained the same since the days of Mikulicz.

All manner of therapeutic appliances have been invented, until now there is a special forceps for the removal of almost every known foreign body, instruments for the application of drugs to ulcerated surfaces, curettes for the removal of sections for microscopic examination, lens attachments for the photographing of pathological lesions, etc. Beautiful photographs have been obtained through the esophagoscope of the various affections that are common to this organ.

Perhaps the most brilliant results that have been accomplished through the use of the esophagoscope, however, are in the diagnosis and abstraction of foreign bodies. It is always a matter of gratification to the internist when a bit of the vast territory that he has gradually been compelled, through force of argument and results, to relinquish to the surgeon, is regained. The removal of foreign bodies from the esophagus, until the esophagoscope came into more general use, was attempted in the dark through the use of long forceps, and if this was unsuccessful, surgery had to be resorted to. If the object remained in the upper part of the esophagus, an external esophagotomy was done, and prior to 1896 this was not an uncommon operation. If, on the other hand, one of the lower points of location was chosen by the object, namely, the level of the bifurcation of the bronchi or the hiatus esophageus, then one of the most difficult operations known to surgery had to be done. Now these objects may be removed with equal ease, regardless of their location, without surgical interference.

During the past year three cases of foreign bodies in the esophagus have come into my hands, and in each case the object was successsfully removed by the aid of this instrument. In a fourth case, in which a foreign body or ulcer was suspected because of the symptoms manifested by the patient, an examination through the esophagoscope revealed the absence of either foreign body or ulcer, as far down as the cardiac orifice of the stomach.

Before turning to these cases, permit me to recall a few points concerning the anatomy of the esophagus which are necessary in the consideration of the technique of introduction of the esophagoscope. In its upper third it lies between the vertebral column and trachea, and then crosses the left bronchus, coming into direct contact with the aorta, passing slightly to the left of the vertebral column and then through the hiatus esophageus in the diaphragm, and for a length of 2½ cm. runs intraabdominally. Its length from the cricoid cartilage, where the esophagus may be said to begin, to the cardia, is 25 cm. From the teeth to the cricoid cartilage the length varies from 14 to 17 cm., making the total length of the esophagus in a straight line from the teeth to the cardiac orifice of the stomach 40 cm. The cervical portion of the esophagus is closed, the thoracic portion remains open and enlarges with each inspiration. The portion between the diaphragm and the cardiac orifice is closed. The width at different portions varies from 12 to 20 mm. The narrowest portions, above which foreign bodies usually lodge, are at the cricoid cartilage, 12 mm., at the hiatus esophageus, 12 to 14 mm., and at the crossing of the bronchus, 17 mm.

The patient often gives misleading statements as to the location of the object, because of his inability to interpret his sensations. This is due, firstly, to the poor supply of nerves of sensation to the esophagus, and, secondly, to the reflex contractions which take place at points above the location of the object. The chief symptoms in all of these cases are the dysphagia, pain caused thereby, and a feeling of indescribable discomfort and pressure. In the cases, which I here report, the patients were able to locate rather definitely, with the finger on the sternum, the position of the foreign body.

Case I.—H. M. R., age thirty-five, teacher. While at dinner on May 8, he swallowed a hard object, which first seemed to lodge back of the tongue. The patient thought he could feel it with his fingers. On the advice of his physician, he endeavored to carry it down with soft food, and was of the impression that he could feel it pass down to a certain point, beyond which he was unable to move it. The pain was not great in the beginning, but he was unable to swallow anything but liquids and very soft foods. Twenty-four hours later he was examined by a laryngologist, who was unable to see anything

with the laryngeal mirror. The symptoms increased, the discomfort daily growing worse, until on May 12, four days later, the patient was sent to me. He was a very intelligent man, possessing none of the stigmata of hysteria. The pharynx of the patient was anesthetized with a 10 per cent. solution of cocaine, and with little difficulty the esophagoscope was introduced. At a point about 25 cm. from the teeth, there was on the posterior surface of the esophagus an ulcerated area, as large as the diameter of a split pea, in the center of which there was a white, glistening object. This object was removed by means of forceps, and was found to be a piece of cellulose, a half inch in length, roled up into a little quill, pointed at one end. The patient was advised, on account of the ulceration, to remain on a liquid or soft diet for a period of a week. He experienced considerable soreness upon swallowing for at least a week after the removal of this object, but the condition gradually improved until within a period of ten days he was able to eat without any discomfort whatever. In this case it must be borne in mind that the foreign body had been in the esophagus for a period of four days, and had succeeded in producing considerable inflammation, with ulceration at the point of lodgment. For this reason the symptoms necessarily persisted longer after the removal of the object than they ordinarily do if removed at once. This object was partially buried in granulations in the posterior wall of the esophagus, just over the bifurcation of the bronchi and in very close proximity to the aorta. It is needless to dwell upon the possible outcome of such a case, had it been permitted to go on indefinitely, or had a more virulent infection occurred as a result of the trauma.

Case II.—Mrs. C. W. S., age sixty, while eating chicken salad, felt an object lodge in her throat, and was unable to expel it through the mouth, or to cause it to pass downward. She endeavored, through swallowing other food, to cause it to go down, but this procedure simply caused greater discomfort and greater pain. She took olive oil and pepsin with no effect. Her "gullet felt very raw," and after twenty-four hours the patient recognized the futility of waiting for the object to pass into the stomach. The throat was carefully examined, but nothing could be seen either in the larynx or pharynx. Because of the patient's definite statements as to the constant location of the pain, which was apparently at, or just below, the cricoid cartilage, a short esophagoscope, 20 cm. in length, was used. After the cocainization of the pharynx, the introduction of the instrument required but a moment with the aid of the esophageal bougie and presented a most interesting picture. What appeared to be a small fish bone was stretched across the esophagus at a point just below the cricoid cartilage. The mucous membrane was considerably reddened and congested but there was apparently no ulceration. To my surprise, the object could not be pulled into the tube by means of the forceps, and after several attempts to withdraw it through the tube, I determined to take a firm hold upon the object and withdraw the tube and forceps simultaneously. This was done. It proved to be a piece of the breast bone of a chicken, triangular in shape, about three-quarters of an inch in diameter. The patient felt instant relief; five days later all discomfort had disappeared.

Great care must be taken in the application of the instrument in such cases as this, in order not to come in contact with the object before the bougie is removed, otherwise the object may be driven deeper into the tissues, or possibly pushed into a lower portion of the esophagus. In cases in which the object lies in the upper part of the esophagus, I feel that it would be better to introduce the instrument under the constant guidance of the eye, rather than with the bougie, but the presence of the bougie makes the introduction easier for the physician and less uncomfortable for the patient. In this case I was unfortunately unable to inspect the area from which the object had been removed, because it would have necessitated the reintroduction of the instrument. This, of course, occurs only when the object cannot be withdrawn through the tube, or if sufficient bleeding occurs after the removal of the foreign body to obstruct the field. While tampons may be used successfully when saliva obstructs the field, they are not very satisfactory when there is a considerable amount of bleeding, because usually before the tampon can be removed through the long instrument, sufficient blood has again collected to obstruct the field. In such a case adrenalin or some other astringent might be tried.

Case III.—Mrs. M. B., age 46, on January 15, at noon, while eating pork, felt a solid body pass into the throat. She made frequent attempts to swallow it, but failed. After a time it passed downward and "seemed to lodge under the upper portion of the breastbone." The patient was absolutely unable to swallow food in an effort to dislodge the object, and all efforts to dislodge it through vomiting, coughing, swallowing, etc., were futile. Her physician made a number of efforts to remove the object, but was unable to do so. The patient was sent to me January 27, about forty-eight hours after the accident. The pharynx, larynx, and upper portion of the esophagus were anesthetized. The instrument was introduced slowly and carefully and the bougie removed as soon as the esophagoscope was passed over the epiglottis. A white mass could be detected diagonally across the lumen of the esophagus, about 27 cm. from the teeth. This was caught at what seemed to be the uppermost end and readily withdrawn under the aid of reflected light. It was found to be a piece of bone, in all probability from pork, about an inch in length and one-eighth to one-quarter inch in width. The patient reported forty-eight hours later, and while she still experienced slight pain and "rawness of the throat" upon swallowing, she was able to take soft food with ease. She was asked to report to me again if the symptoms did not disappear within a few days. Her failure to do so is indicative of the absence of any unpleasant results in her case.

Case IV.—Miss M. M., age 22. Prior to a week ago was in very good health. From time to time, for a year or more, has complained of eructations of gas and occasionally of food. A week ago, after eating some "chile con carne" with a party of friends, she was suddenly attacked with a severe pain, just under the xiphoid process. The pain was so intense and so sharp that she writhed in agony. She described the pain as being of a "sticking, stabbing" character. Several physicians were sent for and hypodermics were resorted to. The attacks came on periodically at short intervals throughout the week, but there was no time when she was entirely free from pain. She was unable to swallow anything without great distress at this point; in fact, was absolutely unable to take anything but liquids. Several times during the week she brought up a small quantity of blood, which she felt sure came up with fluid she had swallowed. It was

not coughed up, and she feels reasonably sure it did not come from the lungs. Excepting for the point of exquisite tenderness over the xiphoid area, which could be very definitely localized with the finger tip, the physical examination was negative. Though somewhat nervous, she could not be considered a hysterical person. A review of the symptoms led to the supposition that either a foreign body had lodged in the esophagus, near the cardiac orifice, or there existed an acute erosion at this point. The esophagoscope was introduced throughout the entire length of the esophagus down to the cardiac orifice and the mucous membrane carefully inspected as the instrument was introduced. The mucous membrane appeared perfectly normal throughout, and nothing that could be interpreted as either a foreign body or ulcer was found. The esophagoscope was then slowly withdrawn and the mucous membranes again inspected and found perfectly normal. In view of the absence of any pathological lesions in the esophagus, I could only interpret her symptoms as that of an ulcer within the stomach, very near the cardiac orifice. The patient was put to bed and given a four weeks' ulcer cure, with good results. I shall not go further into the history of this case, inasmuch as no esophageal lesion was found, but cite the same to show the value of negative findings as well as positive in the use of the esophagoscope.

The following three cases are selected because of the different features of esophagoscopy that they bring out, the first one being a case of a malignant stricture in which the introduction of the esophagoscope was impossible, the second being a case of malignant stenosis in which the diagnosis could be easily made with the esophagoscope, and the third a case of stenosis in an old man in which the diagnosis of a benign stricture could easily be made and the stricture dilated by means of sounds through the esophagoscope.

Case V.—Mr. H., age 54, German. There was nothing of importance in his family or previous history. There was no history of lues, and the patient had been in excellent health all his life. About three months prior to his visit to me he noticed slight difficulty in swallowing. About a month before this he had commenced working in lead paint. This had given alternating spells of constipation and diarrhea and he thought it might have had some effect on his swallowing. The difficulty was at first noticed only when he swallowed large particles of food. They seemed to lodge "just under the end of the breastbone," and he often had to expel them. Liquids, soft foods, and well-masticated particles he was perfectly able to swallow. At this time he was living on soft-boiled eggs, eggnogs, broths, etc., and even liquid seemed to lodge above the pit of the stomach; after a moment he could hear it pass into the stomach with a noise. The patient had lost little if any weight up to this time and felt perfectly strong and well able to do his work. The physical examination revealed nothing of a positive nature, the patient was well nourished, well developed, slightly anemic, but in no sense cachetic. The introduction of bougies showed an almost complete obstruction near the cardiac orifice of the stomach. With great difficulty, a French bougie, size 22, could be introduced. Malignancy was at once suspected because of the suddenness of the onset in a man 54 years of age; he gave no history of trauma and he was in no sense a nervous individual. However, in order to make the diagnosis complete, an effort was made to introduce the esophagoscope. The patient was a very pliable one, willing and anxious that the seat of the trouble should be discovered, and lent us every assistance in our efforts to introduce the esophagoscope. Eight or ten efforts were made, but we were absolutely unable to introduce the instrument. The cervical spinal column was perfectly flexible, and the patient assumed a perfect position. There were, however, two obstacles in the way of the introduction, one being very long incisor teeth, which we did not feel justified in removing because the diagnosis seemed fairly complete without the esophagoscopic examination, and the second a very convex cricoid cartilage. The patient had a large prominent larynx, which protruded posteriorly as well as anteriorly. Small bougies met with partial obstruction here. During the time that the patient was under my observation, he began rapidly to lose weight and strength and was referred back to the surgeon for gastrostomy. This case is recited to show how the most persistent efforts to introduce the esophagoscope in some cases may prove futile. Had there been a reasonable doubt about the diagnosis, two or three of the incisor teeth could have been removed.

Case VI.—Mr. J. C., age 62. Patient had lues thirty years ago, with primary but no secondary lesions. Appendix was removed six years ago. Married at the age of 43, had no children. Until recently he had been an excessive drinker. About six months ago began having a gastric disturbance, characterized by loss of appetite, bloating, eructations of gas; no pain. Began vomiting about two and a half months ago, after almost every meal, sometimes with considerable straining, at other times would regurgitate his food without any effort. Often the food would come up while at the table, when he would return and finish his meal. He found that he had to eat very slowly, chew food thoroughly, and swallow no large particles. In this way he succeeded in taking a fairly hearty meal and retaining it. No blood in the vomitus, no jaundice, no colics. He is thirty pounds lighter than his best weight. Since on a general diet, thinks he has been gaining weight. Patient is very slender, considerably emaciated, bony frame, small, somewhat anemic, no definite cachexia, though the skin is dry. No enlargement of the cervical, or the supraclavicular lymph nodes. Has a typical habitus enteroptoticus. Heart sounds weak, otherwise normal. Lungs negative. Liver dullness displaced downward, beginning at the eighth rib and extending three finger breadths below the free margin of the ribs. One's first impression is that of enlargement of the liver, but the measurements of the outlines show it to be normal in size. The liver is palpable in the epigastrium and somewhat harder than normal liver substance. An effort to introduce the stomach tube met with an obstruction about 40 cm. from the teeth. The smallest sized stomach tube could not be introduced; succeeded, however, in introducing the esophageal bougies 24, 26, and 28 consecutively. A tentative diagnosis of carcinoma of the lower third of the esophagus, or the cardiac orifice of the stomach, was made and the patient was sent to the hospital. Two days later the esophagoscope was introduced and at a distance 38 cm. from the teeth the obstruction was very definitely seen. There extended into the lumen a cauliflower excrescence of a typical granular appearance, seeming to come chiefly from the posterior wall, though the entire circumference was involved. Being 38 cm. from the teeth, it was considered carcinoma of the esophagus. Inasmuch as a total obstruction was imminent, the patient being practically unable to swallow anything, even fluids, a gastrostomy was recommended. Upon opening the abdomen, the lesser curvature and cardia of the stom-

ach were found to be also involved but entirely covered by the ptotic liver which gave the feeling of resistance, spoken of above, in the epigastrium. An enterostomy was done and the patient fed for a period of two weeks into the first loop of the jejunum, after which he died. An autopsy was not obtainable. This was, in all probability, carcinoma of the cardia extending into the esophagus, rather than a carcinoma of the esophagus involving the cardia and lesser curvature.

Case VII.—Mr. S. R., age 50. On January 4, 1907, the patient came to me with the statement that for a period of one year he had had considerable difficulty in swallowing, together with pain in the right hypochondriac region, which was more or less constant and abated for short periods only. Directly over the lower part of the sternum he marked a point where the food seemed to stop. He did not vomit, but belched a great deal of gas. In the beginning there was no pain at the point of apparent obstruction, but he felt as if a stone lay there. After swallowing, and during the passage of the food through the esophagus, he had a "sticky, uncomfortable sensation for a few moments until it entered the stomach." Four months after this condition arose he applied to Dr. Engelbach, who introduced the stomach tube without any difficulty whatever. Two months later, that is six months after the development of the disturbance, he applied to Dr. Rush, who also introduced a stomach tube without the slightest difficulty, and made an analysis of the gastric contents, which showed a mild subacidity. At that time the patient was able to swallow semisolids easily and had swallowing murmurs in 10, 20, and 30 seconds. About a month later, however, both the stomach tube and bougies met with a firm resistance at points from 18 to 20 cm. from the teeth. When the patient applied to me he was still complaining of great difficulty in swallowing, being unable to swallow solid foods, and fluids with difficulty. The pain in the right hypochondriac region, for which no cause could be found, still persisted. When he made an effort to swallow solid food, such as a piece of meat, it would lodge and then through great effort on his part he was able to regurgitate it. Only the small size bougies could be passed and these with considerable difficulty. The esophagoscope was used and was quite readily introduced to a point about 30 cm. from the teeth where a definite stricture was met with, which was to all appearances of a benign character. The mucous membrane was pale and glistening in appearance, showed no evidence of ulceration, granulation, or any neoplasm. Through the esophagoscope it was possible to pass much larger sounds than without. While bougies not larger than French No. 22 could be introduced without the esophagoscope, we were able to introduce Nos. 28 and 30 through the esophagoscope itself. This patient was observed for several months and the diagnosis of benign stricture was confirmed through the continued history. He refused operation and I met with him quite by accident about eight months after his first visit to my office and so far as I could see his condition had in no way changed.

In all of my cases the instruments devised by Killian have been used, with the patient in the sitting posture, as first described by Stoerk, rather than in the reclining posture upon the back or upon the side. The patient sits upon a low stool with someone in a chair behind him, supporting his back, pushing the chest somewhat forward and throwing the head back as far as possible. In this manner the mouth, pharynx, and esophagus are brought into one line. The pharynx was thoroughly anesthetized with a 10 per cent. solution of cocaine. Some recommend 20 per cent., but so far as I can see it has no advantage over the weaker solution and is unquestionably more dangerous. Patients are instructed not to swallow immediately after the applications are made; the esophageal bougie is permitted to extend about six inches beyond the end of the esophagoscope and is introduced with the head dropped forward. As soon as the top of the bougie has passed over the epiglottis, the patient is instructed to throw his head back as far as possible and the instrument is slowly introduced until the end of the esophagoscope is felt to pass over the cricoid cartilage. This sensation is a very definite one to the operator. The bougie is then slowly removed, while the esophagoscope is held in position. The light is then thrown into the instrument through the aid of the panelectroscope, or the Kirstein lamp. It is then slowly introduced under the constant guidance of the eye. In this manner, providing aneurysm has been excluded, there is practically no danger from the introduction.

Though not carried out in all of my cases, I consider the anesthetization of the larynx as well as the pharynx a wise procedure. Otherwise the patient may develop a fit of coughing, which necessitates interrupting the examination, or the withdrawal for the time being of the instrument. A general anesthetic is not necessary, excepting in the case of children, or in adults where a prolonged examination is apt to be necessary. Even in the latter cases, thorough cocainization is usually quite sufficient. When a general anesthetic is used, the patient lies upon his back with the head hanging over the end of the table. The examination is greatly facilitated by the absence of either two or three of the incisor teeth, or the first molars of the superior maxilla, it sometimes being impossible to examine individuals with long incisor teeth. Fortunately, in all but one of my cases I found either upper plates, or two or more teeth absent, which facilitated the introduction of the instrument very much. Two great obstacles in the way of examinations with the esophagoscope are a rigid cervical spine, and a very convex cricoid cartilage. In case No. V the latter condition existed, for the patient had a long, flexible cervical column, was very anxious that the instrument be introduced, and yet despite innumerable attempts we were unable to pass the cricoid cartilage. In the meantime the diagnosis had become so definite that the introduction was unnecessary. After the instrument has been introduced, saliva and mucus are the greatest obstacles in the way of a clear picture. The cocaine stimulates the flow of a viscid mucus, which passes down to the point of stricture and often inserts itself into the end of the esophagoscope, completely clouding the picture. This is not apt to occur except in cases of stenosis of the esophagus or of foreign bodies large enough to prevent the passage of the saliva into the stomach. Until it is removed through the use of tampons or a pump, nothing can be accomplished. I have found a most satisfactory appliance in this dilemma to be a small rubber tube with a bulb at the proximal end. The tube can be dropped into the esophagoscope and slow suction produced withdrawing the saliva. This process may have to be repeated two or three times during a single examination. In other cases this obstacle is not met with at all, and the examination from beginning to end goes along satisfactorily. The success and the usefulness of the esophagoscope depends, as does that of all our mechanical aids in diagnosis, upon the

operator's technique and his ability to interpret his findings. This is true of the cystoscope, the ophthalmoscope, the x-ray, etc., and it is only through constant practice and frequent examinations of the esophagus that such powers may be developed. Those acquainted with the application of the esophagoscope, use it with the same freedom that one does a proctoscope or similar instrument. Though the introduction produces some discomfort to the patient, because of the position assumed, he yields to it readily where the use of the instrument is indicated and suffers no ill consequences as a result. The symptoms produced by obstructions of the esophagus are so unpleasant that patients submit readily to any procedure that promises relief.

SURGICAL TECHNIQUE WITHOUT THE USE OF ANTISEPTICS: WITH REPORT OF FORTY-ONE CONSECUTIVE SUCCESSFUL ABDOMINAL OPERATIONS.

By WILLIAM H. DUKEMAN, M.D.,
LOS ANGELES, CAL.

One master of surgery of to-day advocates a certain technique in the preparation of his patient and of his hands with the aid and use of certain mercurial antiseptics and the wearing of gloves. Another, his rival, advocates an entirely different technique with the aid and use of different mercurial antiseptics and does not wear gloves. A third, a critic, then comes forward and gives his hands a more thorough scrubbing and washing and does not use any mercurial antiseptics or does not wear gloves and has equally good results. He then makes cultures from scrapings of the hands in each case and proves by bacteriological examination that his hands showed less bacteria and less source of danger to the patient than those of either of the others. This convinced me that antiseptics and gloves were superfluous and I would venture to operate by adopting the latter method. And I will here venture the assertion that the time is not far distant when all surgeons will discard antiseptics as they are used to-day, and will confine the technique to simple, thorough cleanliness, and will wear gloves only in septic cases for self-protection.

The first principle in surgical technique is cleanliness and not antiseptics. And by cleanliness is meant as thorough a cleansing with hot sterile water and soap as can be accomplished. By a thorough cleansing is included the scrubbing and washing of every part considered in connection with the operation. This scrubbing of the patient should be done without undue irritation of the parts and should not be done with a brush as is the custom, but with a succession of sterile gauze sponges and a free use of hot sterile water and sterile soft soap. To properly accomplish this the patient is removed from the bed to the surgery, or, better, to a special cleansing room, warm and comfortable, there laid on a table and washed and cleansed and prepared by a clean nurse as per the following instructions, a copy of which is left with the surgery nurse:

FOR THE SURGERY NURSE.

Please prepare my patient for operation as follows:

1. On entering the hospital, give general warm water tub bath, using plenty of soap.

2. Flush colon and rectum with large enema of soap and warm water. And again at 7 P.M. a second and final flushing with normal saline solution.

3. Wash and scrub vagina with warm sterile water and soft soap, then rinse thoroughly, and every three hours douche with 1 per cent. hot, sterile saline solution (temp. 120°).

4. Shave abdomen and pubes, and with a succession of sterile gauze sponges scrub same with sterile soft soap and hot, sterile water, temp. 120°, and rinse thoroughly; then wash same with equal parts alcohol and ether.

5. Now cover field of operation with a thin poultice of sterile soft soap and leave on one to three hours (according to the sensitiveness of the patient). Then remove the soap by five minutes' thorough scrubbing with a succession of sterile gauze sponges and hot sterile water, and rinse thoroughly with hot sterile normal saline solution.

6. A compress of sterile gauze is now placed over and around the abdomen. Secure same by bandage and leave on until removed in operating room.

7. Immediately before patient is anesthetized, see that the bladder is completely emptied (if necessary, patient should be catheterized by sterile method).

8. After patient is anesthetized and upon the operating table, again, with a succession of sterile gauze sponges, scrub the field of operation with sterile soft soap and hot sterile water; rinse thoroughly, then sponge off with ether, then alcohol, and finally irrigate with hot sterile normal saline solution. Then quickly cover patient from shoulders to feet with sterile cover and towels properly arranged for the operation.

9. Have prepared in operating room a plentiful supply of hot sterile normal saline solution.

Wm. H. Dukeman, Surgeon.

Operation.....
Hour.....Day.....Date.....

In emergency cases of course the technique is varied to meet the exigency of the case. In acute cases demanding operation within the twenty-four hours the above program is carried out, but in all cases where time will permit I like to have my patient in the hospital two or three days for preliminary preparation. This consists in the administration of 30 c.c. of castor oil on an empty stomach in the early morning of the first day in the hospital. If the patient is of a bilious nature then .13 gram of calomel in divided doses of .026 gram each is given dry on the tongue at intervals of a half hour on an empty stomach in the evening preceding the morning administration of the oil. If the patient will not take the oil then a saline aperient is given. Nourishment is not given until the effect of the oil has passed off. Then a cup of good hot coffee is given. This is usually followed by further peristalsis. Then a high saline enema is administered. This generally gives the bowels a very complete cleansing and the patient rests. Liquid nourishment only is now allowed, which consists of a cupful of broth or boiled milk, and only at meal times.

The usual high flushing of saline solution is again given in the early evening preceding the morning of operation. The patient then rests for the night.

In the twenty-four-hour patients the calomel or the oil is given at once and followed by same technique as above. By this method there usually is no nausea following the anesthetic and the patient is in good condition to ward off any possible shock, the result of a prolonged operation.

The disinfection of the patient's mouth is a very important factor in the prevention of post-operative nausea and also in the prevention of post-operative pneumonia. The nasal cavities are cleansed by douching with a one per cent. saline solution, and the teeth are scrubbed with one of the chalk tooth powders, night and morning, and the mouth rinsed freely with saline solution after each meal and before bedtime, both before and after operation.

Several examinations are made of the urine, that the condition of the kidneys may not be overlooked.

By kind words and sympathy the patient is gotten into an easy frame of mind, and getting her full confidence is an important factor in averting shock. Worry and fright cause shock.

The technique of the surgeon's preparations is cleanliness as perfect as can be accomplished. Both myself and my assistant avoid, wherever possible, the handling of any pus cases for at least twenty-four hours preceding an operation, and in the handling of such cases gloves are worn to protect the hands. On the night before operation, my assistant as well as myself give our hands a thorough washing with hot water and soap, and with a clean boiled nail brush the nails and fingers and palms of the hands are thoroughly scrubbed, but we never use the brush on the back of the hands or on the arms, for the reason that scrubbing the back of the hands and arms causes more or less irritation of the more delicate structure of the cuticle of these parts and in many cases this is followed by a weeping of the secreting glands which is conducive to infection. For the same reason the nail scraper is never used, as the cuticle adjoining the nail is very likely to be broken. The hands are again as thoroughly washed in the making of the toilet in the morning.

On entering the hospital the surgeon and assistant immediately go to the dressing-room and there remove all outer garments, including shoes. A sterile operating suit is donned, including slippers or tennis shoes.

In the wash room the nostrils are first thoroughly cleansed and then the hands and arms receive their third and final washing as follows: With a clean boiled nail brush, sterile soft soap and running hot sterile water, they are scrubbed for at least five minutes and longer if necessary to be cleaned, then thoroughly rinsed. The hands and arms are then immersed and washed for a couple of minutes in a hot sterile saline solution contained in deep receptacles, one for the surgeon and another for the assistant, then finally washed in alcohol and again rinsed in clean sterile saline solution which makes them soft and pliable. This completes the toilet of the hands. Formerly the hands and arms were immersed for a couple of minutes in a 1-1000 bichloride solution as a routine method, but when we came to consider the inefficiency of this brief immersion of the hands in the bichloride it was considered superfluous and useless and it was abandoned. No gloves are worn, and in no case has there been any perceptible trace of infection.

Being attired in the surgical sterile gown and a gauze head gear, a gauze respirator being placed over the nose and mouth, we are in readiness to proceed with the operation.

All nurses, after as thoroughly washing the hands as does the surgeon, are obliged to wear sterile gloves, for the reason that nurses' hands are invariably septic, due to the constant handling of infected materials. No unnecessary talking is allowed during an operation. Each nurse has her duty assigned and from this there is no deviation.

An experienced anesthetist is essential in aiding to avoid post-operative vomiting and shock. This is an all-important position and no one should be allowed to administer an anesthetic for a prolonged operation but an expert. He also washes and wears sterile gown and cap.

Throughout the operation the hands of the surgeons are rinsed frequently in hot setrile normal saline solution contained in a sterile basin placed to his left. This keeps the hands clean and pliable. In operating, time is an important factor to the welfare of the patient, but this is not allowed to border on being hasty. Every move is done deliberately but gently and with delicacy, and throughout the operation the utmost delicacy and gentleness are exercised in the handling of every part, so there is no bruising of tissue to be left to slough. And from this more than from any one other thing do I attribute the excellent results obtained. There were no cases of shock in the series even in the most critical cases.

No complicated instruments are used. All instruments and ligatures in the tubes are boiled for ten minutes in a one per cent. bicarbonate of sodium solution. The cutting instruments are wrapped in cotton or gauze to protect the edge from injury. One knife with a keen edge is used to divide the skin and subcutaneous fat, a second one for the deeper structures. Immediately on making the first incision with one stroke of the knife through skin and subcutaneous fat, a hot sponge wrung out of hot sterile normal saline solution is applied and compressed on the wound for a few seconds which usually controls all hemorrhage. The use of artery compression forceps is an unusual occurrence and as a general rule uncalled for. The deeper structures are then divided with a clean knife by a few strokes and by blunt dissection until the peritoneum is exposed. All hemorrhage thus far is usually controlled by hot compresses. Perhaps none, or at the most in plethoric conditions only three or four artery compression forceps have been applied.

The peritoneum now being picked up and opened, the finger is inserted, and acting as a guide the peritoneum is divided the full length of the wound with sharp scissors. The operation is then proceeded with according to the case. Now with flat broad gauze pads wrung out of hot sterile normal saline solution the abdominal cavity around the field of operation is as completely shut off as is possible. Retractors are very seldom used. Compression forceps are used only on parts to be removed so that there is no bruised tissue to be left to slough.

Ligatures are tied snugly but not too tightly. Arteries are ligated without clamping before dividing wherever possible; thus avoiding ligation of tissue *en masse* which would later slough and cause trouble; small catgut ligatures are used in all the cases and none larger than No. 2. Hot moist sponges and compresses wrung out of hot sterile normal saline solutions are used to control oozing and for cleansing and drying the abdominal cavity.

All divided or raw surfaces in the abdomen, peritoneum, etc., are closed by being turned in and overwhipped with No. 0, or No. 1 sterile catgut with round-pointed and round-bodied needle, so that when the operation is completed there are no raw surfaces left exposed for adhesions to form.

The abdomen is closed in layers with No. 2 chromatized catgut for fascia and with through-and-through silkworm gut sutures, including the deep fascia, with Hagadorn needles introduced from within outward. The needles are threaded on both ends so that any skin bacteria may not be carried to the deeper structures. Pains are taken carefully to coaptate all divided tissue. Where the wound is not large and the tension not great the subcuticular stitch with silkworm gut is used in place of the through-and-through sutures. Only dry plain sterile gauze dressings are applied and snugly strapped with sterile adhesive bands, but not too tightly.

There were no antiseptics of any kind used, no matter what was the condition. There were no stitch abscesses and no unlooked-for complications, and all recovered in the shortest possible time. The shortest time in the hospital was seven days,

the longest thirty-five days, average time fifteen days.

After-Treatment.—In weak patients and when the operation is a prolonged one, a high warm (temp. 110°) enema of sterile normal saline solution is administered before the patient leaves the operating table.

Strychnine, adrenalin, or other so-called post-operative stimulants are not used. Should the patient suffer much pain, which is very rare, a hypodermic of .008 gram morphine is administered; a second one is very rarely required.

A faithful and competent nurse is placed in charge with instructions not to leave the patient one moment alone, and after three or four hours to see that the bladder is emptied, and to use the catheter, only when absolutely necessary.

The patient is allowed to drink a few swallows of water soon after awakening from the anesthesia. Hot water is preferable. When there is vomiting of bile, a cupful of hot water is given, which is usually immediately rejected and which washes out the stomach as well as could be done by the use of the stomach tube, and the patient much prefers it. This, with a mustard plaster placed over the pit of the stomach, is all that is required. Vomiting after operation occurred in less than one-third of the cases.

After twelve to twenty-four hours, hot broth (one to two ounces) is given every three hours and only liquid nourishment is allowed for the first three days or until the bowels have been moved. After this the patient is kept on light semi-liquid or soft food given at meal time only for the first week and never in large portions. I do not give milk unless the milk is first boiled and agrees with the patient. I have learned that patients do much better by keeping them a little hungry so they relish their meals, than by crowding their appetites.

If, after twenty-four to thirty-six hours, there is much gaseous distention of the bowels the rectal tube is inserted. Should this not bring relief, an enema consisting of quinine, .65 gram, dissolved in 16 c.c. whiskey with 60 c.c. water, is administered, which is usually sufficient to bring down the gas. The bowels are moved on the third or fourth day by administering .13 gram of calomel in divided doses if the patient is a bilious person, in others by a dose of castor oil followed by a low soap and water enema, or by a high enema consisting of magnesium sulphate, 30 grams, dissolved in a litre of warm sterile water.

The operations were all performed during the past three years at the Pacific and the Good Samaritan Hospitals, and all the patients are alive and in good health to-day except one, who died of pulmonary hemorrhage five months after operation.[1]

The following is a brief résumé of the operations, which for convenience are divided as follows:

4 Hysterectomies: 2 total hysterectomies for carcinoma uteri, 1 for ten-pound fibroid uterus, 1 for two-pound fibroid uterus. 15 Abdominal Sections: 1 for gallstones, 8 for removal of pus tubes, 6 for chronic salpingitis, 2 for cystic and degenerated ovaries, 2 for cysts of broad ligament, 1 for dermoid cyst, 1 for tuberculous peritonitis, 1 for ectopic gestation.[2] More than one pathological condition existed in some of the above which accounts for the surplus in numbers.

Two herniotomies, both right inguinal; one of the hernias was strangulated and was operated on at a farmhouse after midnight by candle light.

Twenty appendectomies. In three cases the appendix was gangrenous, and in two of these there were large abscesses. The appendix, however, was removed in each case, and in these cases only of the whole series was drainage used. In two cases the appendix was adherent and communicated with a pus tube. In six cases the operation was for recurrent appendicitis in the quiescent stage. The others were for acute appendicitis.

The age of the patients varied from 6 years to 59 years.

Thirty-seven of the cases were in my own private practice, three were for Dr. F. R. Frost, one for Dr. A. D. Houghton. One patient only has a ventral hernia. This was in a case in which drainage was used in a very difficult appendectomy on a very large fleshy woman. The hernia appeared about five months after the operation. The patient wears a well fitted bandage and as it does not cause her any trouble and she enjoys the best of health she prefers not to undergo another operation.

Dr. F. D. Bullard administered the anesthetic (ether) to most of the patients, and Dr. Arthur Godin assisted me in nearly all the operations.

March, 1908.

EPILEPSY IN PRIVATE PRACTICE, ESPECIALLY THAT FROM REFLEX CAUSES.

By CHARLES G. POLK, M.D.,

PENSAUKEN, N. J.

The treatment of epilepsy is ordinarily so unsatisfactory that there exists a tendency on the part of the general practitioner to be content with prescribing the bromides, and there he stops. These, at least, decrease the number of seizures, and as for permanent results from any course of treatment, he is skeptical. He has studied the disease in the text books, or possibly followed the proceedings of the National Association for the Study of Epilepsy, and there has been set before him theories by some authorities which were in turn denied by others. Epileptiform convulsions from reflex causes and idiopathic epilepsy are alike to him. He has been told by equally learned students of the disease that reflex epilepsy exists and that it does not exist.

Little wonder that he fails to search for any underlying defects in his patient that may cause the seizures. Too often an epilepsy, reflex in its nature, becomes permanent when in its earlier stages it would have yielded to treatment with the defects corrected. The writer has searched in the proceedings of the National Society for a single course of treatment that has not been set aside as valueless by other authorities entitled to equal respect and credence. Thus one authority will dwell on the value of hypochlorization, or the withholding of free salt from table food, and another will declare it to be without benefit; one will urge a general diet permitting veal, peas, beans, and coffee, while another will urge abstinence from all of these and insist upon the most rigid dietetics; and even upon the value of the bromides the profession is divided.

One school of students of the disease is so fixed in the belief that epilepsy is never the result of reflex causes that when the evidences are presented, in the words of Dr. S. Weir Mitchell, they exclaim: "I neither believe nor disbelieve," or with Dr. Frederick Peterson they declare that "epilepsy cured by the removal of reflex causes is not usually genuine epilepsy."

It is granted that epilepsy is a disease with which the profession is groping in the dark. This is especially true with idiopathic epilepsy, but there exists an epilepsy, or, more properly speaking, there exist epilepsies, from reflex causes amenable to treatment when the sources of irritation are removed, especially in the early stages of the disease. It is to these that I wish to direct attention, and failure to search for such hidden causes of so grave a disease constitutes almost criminal negligence. It has been truthfully said "epilepsy is not a single prescription disease. The time was, but is no more, when we say 'this patient has epilepsy, give him bromide.'" This view has been held to the extent that some have practically abandoned the bromides, but except in a certain few cases where the bromides do actual harm they will be found useful as a palliative in connection with other medicinal and especially dietetic and hygienic treatment. The bromides alone have probably never effected a cure. In conjunction with other treatment they accomplish results that otherwise could not be secured.

No less an authority than Dr. Spratling has declared that in properly selected cases he believes 25 per cent. of cures can be effected. This is 20 per cent. more cures than shown by the statistics from our epileptic colonies. If Dr. Spratling means cures can be effected in 25 per cent. of cases of idiopathic epilepsy, that would seem rather too large, in view of our present limited knowledge of the disease, but if he includes the cases resulting from reflex causes the expectation is not too great. That there are many such cases I believe is becoming fast recognized.

Epileptiform seizures are frequently the result of uterine troubles, eyestrain, gastrointestinal disturbance, or some other irritation often so hidden as not to be easily discerned. These probably exist in persons of neurotic heredity, otherwise convulsions would not result. It has been truthfully said that thousands have these abnormalities and do not suffer from epilepsy, but that is no reason for denying that they are the source of epileptiform convulsions in others who come from a neurotic root stock, or even if that is not the case; like conditions do not always bring about the same results in different individuals.

Again other authorities will point to the fact that thousands of epileptics have none of these reflex causes to ascribe to their disease. It is not claimed that epilepsy in all or in a majority of patients is due to reflex causes, but there unquestionably exist cases that in all respects resemble idiopathic epilepsy, and when certain sources of irritation are removed, such patients are free from seizures. It may be said that if that be so the patient does not suffer from idiopathic epilepsy, which in all probability is true.

The treatment of epilepsy, with our present limited knowledge of the disease, must be largely experimental, the physician studying each case and noting the results of the several courses of treatment. I say several courses of treatment because he will not do his entire duty in following any particular line and ignoring all others. He will note the result of each and adopt that which promises the best results.

Passing to the hygienic treatment of the patient, it may be said that this is at least of equal importance with the medicinal. A course of treatment along comprehensive lines should be mapped out and the patient be required to give reports as to his adherence to it. A copy of the following rules may be given him. They do not cover every case, but there can be no mistake in the observance of them: Have meals regularly, with the last meal of the day early and light. Do not eat until there is a sense of fullness. Do not eat peas, beans, veal, much meat, or cereals. A vegetable diet is the best. Fish and milk are permissible. Use as little salt in the food as possible and forego tea and coffee. Do not eat much at one sitting. Keep the bowels free and the intestinal tract aseptic by the use of some antifermentative like salol or betanaphthol. Flush the colon frequently. Take warm salt baths, not remaining in the water sufficiently long to fatigue. Sleep with the head high and keep the feet warm at all times and especially at night. See that any defects in the eyes are corrected and do not use the eyes a long time without resting. If glasses are worn, have the frames straightened at regular intervals. Take as much out-door exercise as possible without fatiguing. Spinal douches and massage should be taken regularly. If seizures come early in the day take 15 grains of bromide of sodium before retiring.

Finally, let me strongly recommend that the epileptic or some member of his family keep an accurate record of every seizure, ascribing what he may believe to be the exciting cause. This will serve both as a guide to the physician regarding the value of his treatment and enable him to advise as to the daily habits of his patient.

Chronic Appendicitis in Women.—S. Handley said in a recent paper before the West London Medico-Chirugical Society that the study of chronic appendicitis had been retarded by two causes; first, by the erroneous belief that an appendix free from adhesions is necessarily a healthy appendix; secondly, by the divorce which in England exists between the practice of general surgery and that of gynecology. The most striking symptoms of chronic appendicitis were located in the female pelvic organs. Of these the most constant and important was dysmenorrhea. The history of a painful menstrual period precipitated (or brought back after its cessation) by what appeared to be an attack of acute indigestion, was very characteristic of chronic appendicitis. But the main object of his paper was to show that chronic appendicitis in women was frequently accompanied by a definite physical sign. This sign was an enlargement of the right ovary up to double its normal size, owing to the congestion and lymphatic stasis produced by the near neighborhood of an inflammatory focus in the appendix. In such cases the diagnosis of chronic ovaritis was usually made, and futile gynecological treatment was often carried out for long periods. In one of his own cases appendectomy cured a patient who had submitted without benefit to douching, blisters, tampons, and local applications to the cervical canal, over a period of five years. The appendix was free from adhesions, and its lumen contained a small collection of pus.—*British Medical Journal.*

Arthropathy in Rötheln.—D. A. Alexander has reported the case of a young man of twenty-four years, who, after a few days of sore throat, stiff neck, malaise, and moderate fever, developed a rash having the distribution and appearance of German measles, and accompanied by an enlargement of superficial glands, notably those of the neck. Before the exanthem had faded, the patient began to complain of stiffness and tenderness in the knees and ankles, and soon all the interphalangeal joints of the fingers presented the spindlelike swelling commonly seen in rheumatoid arthritis. There was no exacerbation of temperature, and neither cardiac nor other complication, and a fortnight from the appearance of the rash all the symptoms were subsiding, and in the following six months only an occasional transient stiffness in the fingers reminded the patient of the attack.—*Lancet.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, August 1, 1908.

ALLERGY.

AN unvaccinated person reacts to the inoculation with the virus of cowpox by a well-known series of phenomena which appear forty-eight hours after the vaccination, the immediate result of the procedure consisting only in the formation of a simple scab at the site of the scarification. An individual who has previously been vaccinated behaves in an altogether different manner; within twenty-four hours the site of the scarification is swollen, red, inflamed, these appearances being accompanied by unpleasant subjective symptoms of itching and slight pain. The previously vaccinated person, accordingly, though immune in one sense, in another has become even hypersensitive to the action of the virus. But while the symptoms and signs in his case disappear in a short time, the person vaccinated for the first time goes through the regular sequence of the phenomena which we call vaccina or cowpox. Both persons, then, react to the virus, only the reaction in the revaccinated individual has undergone a qualitative and a quantitative modification. This is the simple observation which v. Pirquet puts at the head of an exhaustive article on "Allergie," in Vol. I. of the recently published "Ergebnisse der inneren Medizin und Kinderheilkunde." Such changed reaction is observed in many instances of experimental and natural disease; to it belong "serum disease," or the hypersensitiveness to the injections of horse serum; urticarias caused by the repetition of injections of other proteids foreign to the organism; hay-fever, or the accentuated reaction to the pollen of plants; the above-mentioned phenomena of revaccination; the newly studied cutaneous and conjunctival reactions to the local applications of tuberculin, as well as the long-known appearance at the site of puncture in the subcutaneous use of tuberculin; and a host of others of the same general character.

Two substances are probably necessary for the production of the reaction discussed: the one which acts in toxic fashion at the repetition of the inoculation, to which v. Pirquet has given the name "allergen," and the bearer of the hypersensitiveness, "ergin," in the organism affected. The applications of the study of allergy are twofold in character: the reaction may be sought in order to determine the presence of specific "allergens" in the organism, which decides whether a certain pathological process has taken place in the past, or to differentiate the allergens from one another by the differences in the reactions of animal organisms to them. Indeed, Rosenau and Anderson have proposed to differentiate proteids from substances derived by their decomposition by the different manner in which guinea pigs react to these substances. The practical importance of the subject has been especially evident in the recent studies of the local reactions to tuberculin. The scientific interest of it consists in the new insight into the pathological processes which the study of allergy promises. As an instance of this, it may be mentioned that v. Pirquet's studies have led him to the conclusion that the present idea of the period of incubation in infections as caused by the time taken for the multiplication of the infecting organisms is incorrect; according to him, it is determined by the reaction of the infected organism—that is, by the time taken to produce antibodies, the interaction of which with the infecting agents or their products results in the appearance of the phenomena of disease.

It is thus seen that this new development in the study of the general problem of immunity is of interest both to the practical student of disease and to the scientifically trained laboratory worker. The authoritative article of v. Pirquet, only a portion of which we have been able to notice in the above lines, is, therefore, a welcome statement of the general progress in this particular field of scientific medicine.

WHAT DOTH IT PROFIT?

Now that the German Protos and the American Thomas automobiles have reached Paris as the two of the six original contestants to complete a journey of more than twenty thousand miles, one may be allowed to reflect upon the purposes and results of "the race." From a medical standpoint, the test was a matter of human endurance rather than a trying-out of the relative merits of complicated mechanisms. If the winners had not been endowed with the strength of Hercules and the patience of Job, they could never have taken their machines into the French capital at all, no matter how favorable all other conditions might have been. It was entirely a matter of vim, will, and dogged determination to succeed at all hazards.

But while these qualities are excellent in themselves and compel our respect, it is not pleasant to see them utilized in advertising schemes. They are on a par with the restless and dare-devil spirit of the high diver and the leap-the-gap enthusiast. While such feats are being performed we look on somewhat aghast and when they are over we applaud somewhat lustily, yet there must always be a deep-seated feeling of regret for the foolhardiness and abject disregard for life with which no one has a right to trifle. Our sympathy must go out to all unfortunates who through force of circumstance are obliged to earn a living in such hazardous fashion. To be sure, there is always a sense of elation when one can defy the laws of Nature and come out seemingly victorious, but there is a penalty for such defiance which, if not swift and immediate in its dealing, is, nevertheless, certain to come in future days or years.

It can scarcely be gainsaid that the purpose of the contest under consideration was a purely commercial one, indulged in by rival manufacturers and engineered by great newspaper enterprises as a means of securing copy. Therefore, the scheme as

previously planned was likely to reap dollars and distinction for the corporate concerns, but only the latter, possibly, for the individuals who were foolish enough to risk life and limb in this "manly sport." As for the result, this simply shows that it is possible to take an automobile pretty much anywhere on the face of the earth where railroads and ships can be pressed into service in case of emergency. That is a matter which could have been accurately guessed at long before the actual performance of the experiment. As for the drivers and their companions, they have exposed themselves to an endurance test as foolish as, but much more severe than, the horseback tests to which aging officers in our army were recently forced, and if they have come out without immediate hurt they will owe their escape to their youth and resiliency. What the remote results of their nerve-racking trial may be time will show.

REMINISCENCES OF THE AMERICAN SURGICAL ASSOCIATION.

The American Surgical Association was founded in 1879. Its life has been full of interesting features and the names of some of the greatest surgeons have been in the list of its members. Reminiscences of the early days of the association are told in the June number of the *Annals of Surgery* by J. Ewing Mears, one of its original members, who thus places on record some of the notable events which occurred in the first quarter of a century of its existence. He eulogizes Samuel Gross, the founder of the association, a great surgeon, the author of monographs and textbooks, and the pioneer worker in pathological research in this country. Dr. Gross, appreciating to the fullest extent the value of the social intermingling of members of the profession as a means of promoting interchange of thought, at the time of the meeting of the American Medical Association at Atlanta in 1879, called about him a few of the prominent surgeons there assembled and founded the American Surgical Association. There were forty-six original members and the membership was limited to one hundred, a number which was later extended to one hundred and twenty-five. Mears gives chronicles of the early meetings, which were chiefly held to perfect the organization of the association, only a few scientific papers being read. In 1884 appeared the first volume of the "Transactions"; it included all the papers read since the foundation of the society. In the early days of the Association sixty minutes was the time permitted for the reading of a paper, but this was gradually reduced, until to-day only fifteen minutes are allowed. Mears urges in his article that the time limit be again extended, as a quarter of an hour appears to him too short a time for a writer who has given considerable thought and work to the preparation of his paper. Better fewer papers with ample time for their reading and discussion than a mass not fully read or discussed in a proper way.

After a few years of existence a feeling was expressed that the interests of the association would be promoted in having a permanent place of meeting, and Washington was selected in 1884. In 1892 this plan was again changed, and it was decided to meet every third year in Washington in connection with the triennial Congress of American Physicians and Surgeons. Mears admits that much that is interesting and instructive is to be seen and enjoyed at the various meeting places, yet believes that a fixed habitation would contribute to a more serious execution of its business, its scientific work. He suggests that the selection of a permanent meeting place for the association might result in the erection in Washington of a building suitable for its purposes, one which would lend solidity and dignity to the association.

Mears' interesting account of the most important events which transpired in the early days of the association makes very clear the fact that American surgery to-day owes much to the American Surgical Association, and that the latter will continue to be a school for mutual instruction and improvement.

An Original Method of Facilitating Intralaryngeal Operations.

In the issue of the *Lancet* of July 11, 1908, Cyril Horsford describes a method of more ready access to the larynx in those simple operations, such as removal of tumors, etc., not calling for laryngofissure. His paper illustrates the truth of the old statement that there is nothing new under the sun, for he quotes Sir Felix Semon as having found the method described in a German book published some forty years ago, but it is doubtless new to the present generation of laryngologists. Many devices have been brought forward for lifting the epiglottis up out of the way in order to get a good view of the laryngeal interior. Horsford carries out this idea, but goes a step farther. He passes a suture through the tip of the epiglottis and brings the ends out over the tongue, holding them by means of a clamp forceps. The patient then holds the tongue in the ordinary way. The author figures one or two special forms of needle holders he has used in the passage of the suture. He sprays the pharynx thoroughly with a 10 per cent. solution of cocaine. With a laryngeal syringe a little more of the solution is dropped on both surfaces of the epiglottis. A little adrenalin applied in the same way prevents bleeding and helps matters generally. All swabbing or brushing of the parts is carefully avoided, for this usually causes involuntary coughing, which is unnecessary and should be avoided. Horsford gives the histories of four cases of benign tumors removed from the larynx in the manner advocated by him.

Causes of Mortality in Diphtheria, Despite the Use of Antitoxin.

The value of antitoxin has been so universally accepted by physicians at the present day and its use is so general both as a prophylactic and as a curative measure that the inquiry is timely as to what is the cause of death in those patients who succumb to the disease after having received injections of antitoxic serums, the mortality of diphtheria, in spite of antitoxin, being still 10 per cent. With a view to the determination of this question, Martin (*Bulletin Médical*, April 25, 1908) has made use of the material collected from the service of the Hôpital Pasteur from 1900 to 1908, including 853 patients. Of these patients, eighty-three died, but we find that twenty-eight of them died within twenty-four hours

of their entrance into the hospital, and there was not time for them to have received the full benefits of the serum. The mortality was 9.73 per cent. One-third of all the deaths are thus seen to be due to the failure of physicians to recognize the expediency of injecting the serum early in the disease, and of injecting it in all doubtful cases of membrane in the throat without awaiting a bacteriological diagnosis. Of the patients who died within twenty-four hours of entrance, the majority were very young infants from most unhygienic surroundings. These might have been saved by a prophylactic injection of serum. The other prolific causes of death under two years are laryngeal complications necessitating intubation, and often resulting in bronchopneumonia. In older children and adults some deaths result from mixed infections, and might be prevented by early and complete isolation. The remainder of the deaths are later in the disease in patients who show late symptoms of poisoning. A local cure is obtained by the serum, but the absorbed poisons affect the renal, hepatic, and suprarenal functions, and result in death in a state of extreme intoxication. The urine becomes scanty, with a large amount of albumin, or gastrointestinal symptoms and clay-colored stools give evidence of hepatic insufficiency. In the suprarenal capsules are found cellular necrosis and hemorrhages. The remedy for this late intense intoxication is the injection of large doses of serum as soon as unfavorable symptoms appear. Thus the mortality may be greatly reduced by earlier injections of serum and by larger injections late in the disease.

Operation for Pulmonary Embolism.

Arteriotomy for pulmonary embolism was proposed by Trendelenburg in April of this year before the Congress of the German Surgical Society. Since then he has been able to observe two cases of this accident in which the bold operative procedure recommended by him was used. In the first case, treated by Sievers, the emboli were successfully removed and the patient recovered from the immediate effects of the accident; she died, however, fifteen hours later, with symptoms of progressive heart failure. In the *Deutsche medizinische Wochenschrift* for July 2, 1908, Trendelenburg reports a second case, in which he operated personally. It occurred in a tabetic patient after a spontaneous fracture of the femur, and within a few minutes of its occurrence the patient was suffering from intense dyspnea, was almost pulseless, and showed all the signs of quickly impending death. When the pericardium was opened and the pulmonary artery exposed the breathing of the patient had already ceased and the pulsations of the arteries were imperceptible. The artery was divided and four long thrombi were removed from its lumen. Artificial respiration was started and the vessels began to pulsate once more. This patient also recovered from the effects of the embolism and the operation long enough to live in some comfort for thirty-seven hours. The autopsy disclosed the existence of an additional embolus in a branch of the artery not explored during the operation as well as an extensive secondary hemorrhage from the internal mammary vessel. The pericardium, however, was free of blood, showing that the suture of the thrombosed vessel was tight. Trendelenburg concludes that the mistakes committed in this case could be easily guarded against in the future, and the operative treatment of pulmonary embolism may soon be rewarded with a complete success. The accident is so uniformly fatal that the bold procedure recommended seems justified. Medical treatment in this serious emergency is almost synonymous with awaiting the death of the patient, and past advances in the technique of surgery contain in them the promise that the difficulties of operating upon the great vessels will soon be in great measure overcome.

The Nonspecificity of the Lecithin Test.

After Porges and Meier discovered that the blood serum of syphilitic patients mixed with an emulsion of lecithin caused the latter to become fixed, Weil and Braun found that the same reaction took place in two out of five typhoid patients in whom syphilis could be excluded. Recently the latter two observers (*Wiener klinische Wochenschrift,* April 30, 1908) examined the serum of patients suffering from malignant disease and found a positive lecithin reaction in eight out of sixteen. All other diseases which could possibly have given the reaction having been excluded, they attributed the positive reaction to the presence of the tumor. The two typhoid patients in whom the reaction was positive gave a positive Widal in dilutions of one to four hundred, while those in whom the lecithin reaction was negative did not give a positive Widal in dilutions higher than one to one hundred. From this observation they concluded that a positive lecithin reaction, like the positive Widal in high dilutions, depended upon the activity of the serum (upon the number of antibodies). Furthermore Tojosumi has shown that the positive lecithin reaction obtained with the serum of healthy oxen is due to the antibodies present. This fact and their findings in typhoid patients led Weil and Braun to believe that there must be antibodies in the serum of cancer patients who give a positive lecithin reaction. These investigators have not demonstrated the nature of the antibodies, but their experiments do show that the lecithin test is probably caused by antibodies and that it is not a specific test for syphilis, at any rate not as it is used to-day.

Transplantation of Embryonal Tissues.

The Cohnheim theory of the etiology of malignant tumors would obtain its greatest support if the experimental production of such a tumor by means of transplanting the undifferentiated tissues of animal embryos could be effected. It is no wonder, therefore, that numerous workers are occupied with this phase of experimental study of tumors. In the *Russkii Vrach* for June 21, 1908, Dr. Tisenhausen reports the results obtained by him in working with the tissues of the hen's egg in the various stages of its development. The transplantations were made into the anterior chamber of the eye, into the combs, and into the spleen, brain, peritoneal cavity, and other regions and organs. Tumor-like structures having the characteristics of teratomatous new-formations were obtained by this method in about one-half of the experiments, the muscles of the chest proving to be the most favorable sites for the growth of the transplanted tissues. In some cases the transplanted bit of tissue increased to ten or twelve times its original size, its cells showing numerous mitotic figures, while the neighboring cells of the host appeared degenerated and atrophied. None of the transplanted tissues, however, persisted in their development, so that in no case anything closely similar to the progressive growth of a malignant tumor could be obtained. Thus these experiments have been followed by negative results so far as the main

question at issue is concerned. The data obtained and the illustrations of the conditions found in the transplanted tissues will, nevertheless, prove of value to all who are interested in the experimental study of the etiology of malignant tumors.

ALLEGED PROFESSIONAL OPPOSITION TO VIVISECTION.

A FEW weeks ago we received a list of physicians who had signed an appeal for the restriction or the abolition of vivisection published by the New England Antivivisection Society of Boston, Mass. As the paper is without date we were obliged to take the last edition of Polk's Medical Directory in order to look up the standing of these physicians. The interesting result is as follows: Of 162 names, 73 were not in the directory at all. As to dates of graduation the following is the record: 1898 to 1908, 1; 1888 to 1897, 7; 1878 to 1887, 31; 1868 to 1877, 24; 1858 to 1867, 10; 1848 to 1857, 5; 1838 to 1847, 2; date of graduation omitted, 9. As to institutional appointments and private practice the following are the data: Minor positions in unimportant medical schools, 4; small hospitals, 3; dispensaries, 2; asylums, 2; retired from practice, 5; druggists, 1; no appointments, 145. Since the Science of Bacteriology came into being about 1880 and was not widely recognized for several years, it follows that of the physicians signing this circular, who could be traced, only eight were graduated under modern teaching, namely, those who had received degrees since 1888. Any circular of this kind intended to influence public opinion, issued in good faith, should be made correct to date. The 73 names not in the directory may in part be those of physicians who have died or changed their residences. Both are grounds for correction. A vast majority of these physicians in the list live in places having no medical reference libraries giving opportunity for a full investigation of modern medical science and its advances.

News of the Week.

Death Rate in New York.—For the week ending July 18, the death rate in New York was 18.48 per thousand. Last year the rate for the same week was 18.93. For the Borough of Manhattan the rate was 17.18. Diarrheal diseases caused the deaths of 426 children, and there were 172 deaths from pulmonary tuberculosis. Twenty-seven deaths from sunstroke were reported.

Protection of Lives of Infants.—The Chicago Health Department, through its vital statistician, has compiled figures according to which more than 63,000 infant lives have been saved during the twelve years from 1895 to 1907, as compared with the previous twelve years, the death rate having been reduced from 6.13 to 3.18 per 1,000 of the total population. This decrease is thought to be due very largely to the education of mothers in the care of children during hot weather. Since 1900 there has been a large influx of immigration of the Slavic races, and among these people the infant and general mortality is very high. The Chicago City Council has transferred $10,000 from the contagious disease fund to a special fund for the care of children. On July 20, seventy-five physicians were assigned to duty in those parts of the city in which, during 1907, the infant death rate exceeded 7 per 1,000. Thus the Fifth District, along the west bank of the river, will have thirty-four medical inspectors, and the Fifteenth District, which includes the mouth of the Calumet River, six inspectors. These medical officers will call at every home in the district and instruct the parents what to feed their babies and how to care for them. It is hoped that notable results will be accomplished by this work.

A Medical Day in Eastern Pennsylvania.—A gathering of medical men was held at Willow Grove, near Philadelphia, on July 22, under the auspices of the County Medical Societies of Berks, Bucks, Chester, Delaware, Lehigh, Montgomery, Northampton, and Philadelphia. The exercises comprised a dinner, followed by addresses by Dr. J. C. Attix, who extended a welcome on behalf of the management of the park; Dr. Albert M. Eaton, President of the Philadelphia County Medical Society; Dr. William L. Estes of South Bethlehem, President of the Medical Society of the State of Pennsylvania, who spoke on "Fraternalism in Our Ranks," and Dr. Joseph D. Bryant of New York, a former President of the American Medical Association, who spoke on "The Importance of Medical Organization."

The Blind for Telephone Operators.—In Texas the experiment of using blind persons as telephone operators has been tried with great success. The keen sense of hearing possessed by those who have no sight is an advantage, and they learn quickly to manipulate the keyboard by the sense of touch. The occupations in which the blind can engage are so limited that this field, which, if available, would be almost unlimited because of the great extensions of telephone systems, seems worthy of investigation.

Rats Defy Poison.—The New Orleans Board of Health has announced that the experiments undertaken to rid the city of rats by poisoning them have failed. The dangers of the importation of the plague from South America and its dissemination by the rodents prompted the attempt to exterminate them. The Board will now watch the success of the rigid cleaning up of all sorts of refuse as an exterminator.

Cocaine Seller Punished.—A man, recently convicted of selling cocaine, was sentenced on July 21 to one year and six months in State prison, the maximum sentence.

Christian Science Death.—The Coroner of the Bronx is investigating the death of a young woman, after several weeks' illness, without medical attendance. Two "healers" of a Christian Science Church, of which she was a member, had treated her.

The Syracuse University College of Medicine announces the following changes in its faculty: Dr. Frank P. Knowlton, associate professor of physiology, Dr. H. S. Steensland, associate professor of pathology and bacteriology, and Dr. H. D. Senior, associate professor of anatomy, have been advanced to full professorships in their respective subjects. Dr. E. N. Pattee, professor of chemistry in the College of Liberal Arts of the University, has been given a seat in the faculty of medicine. Minor appointments include that of Dr. R. H. Hutchings, medical superintendent of St. Lawrence State Hospital, as lecturer on orthopedics, and that of C. V. Morrill, recently assistant in zoology in Columbia University, New York, as lecturer on histology and embryology. Commencing in 1909, the entrance requirements will include the satisfactory completion of one, and after October, 1910, of two, full years of a science or arts course in a college recognized by the Regents of the State of New York, or the equivalent.

Dr. E. B. Sanborn, for nearly thirty years Deputy Health Officer of the Port of New York, has resigned, and will retire to his old home in

Maine at the end of August. Dr. Sanborn was born in Maine, and was graduated from the College of Physicians and Surgeons in this city in 1867. He was appointed Deputy Health Officer in 1879, and has served in that capacity under Health Officers Vanderpool, Smith, Jenkins, and Doty. He will be succeeded by Dr. Edward S. Rimer.

Dr. William P. Spratling, for nearly fourteen years the medical superintendent of the Craig Colony of Epileptics, has been elected to the chair of nervous diseases and physiology in the College of Physicians and Surgeons, Baltimore, and will move to that city in the fall.

Dr. C. A. L. Reed of Cincinnati was recently appointed a Chevalier of the Legion of Honor by the French Government.

Dr. Joseph E. Lumbard has been appointed anesthetist to the Mt. Sinai Hospital in this city.

A "Clean Milk" Exhibit.—Preparations are being made by the New York Committee of the International Congress on Tuberculosis to hold a clean milk exhibit during the three weeks of the tuberculosis exhibition at Washington, from September 21 to October 12, 1908. The cooperation of a number of dairy owners has been obtained. The exhibit will include photographs of dairies, statistical charts, Petri plates of the bacteriology of milk, and illustrations of tuberculin tests in cattle, and will also have a small working dairy with tuberculin tested cow, skilled attendant, sanitary utensils, shipping cases, and all sanitary appliances for the marketing of a clean milk. In view of the fact that Mr. Nathan Straus is preparing for the exhibition a duplicate of the pasteurization plants already erected by him in Heidelberg, Brussels, and Berlin, the exhibition at Washington will afford an opportunity for a comparative study of the two methods of marketing milk, viz., (1) pasteurized, and (2) unpasteurized but clean.

The Tri-State Medical Society of Illinois, Iowa, and Missouri will hold its sixteenth annual meeting at Ottumwa, Iowa, on Tuesday and Wednesday, September 8 and 9, 1908. The announced program is too long for detailed mention, but includes a number of important papers on tuberculosis and its treatment, surgery of the gall-bladder, and the social evil. The title of the President's address is, "Recent Progress in Medicine and Surgery." The officers of the society are as follows: *President*, G. O. Cuppaidge, Moberly, Mo.; *Vice-Presidents*, C. C. Cochran, Jacksonville, Ill., and Felix W. Garcia, St. Louis, Mo.; *Secretary*, Joseph E. Chambers, St. Louis, Mo.; *Treasurer*, Emory Lanphear, St. Louis, Mo.

The Addison County (Vt.) Medical Society, at its annual meeting, held recently, elected the following officers for the ensuing year: *President*, Dr. G. F. Edmonds of Bristol; *Vice-President*, Dr. S. C. Phelps of Vergennes; *Secretary*, Dr. P. L. Dorey of Middlebury; *Treasurer*, Dr. S. S. Eddy of Middlebury; *Librarian*, Dr. M. H. Eddy of Middlebury.

The Oxford County (N. H.) Medical Association held its annual meeting in Gorham on July 6. Officers were elected for the ensuing year, as follows: *President*, Dr. Cobb of Berlin; *First Vice-President*, Dr. Wheeler of West Paris; *Second Vice-President*, Dr. Wright of Bethel; *Secretary-Treasurer*, Dr. Hutchins of Rumford; *Executive Committee*, Dr. Williamson of Portland, Dr. Stanwood of Rumford, and Dr. Bradbury of Norway.

The Maritime Medical Association (Canada) met at Halifax during the first week of July. The following officers were elected for the ensuing year: *President*, Dr. P. C. Murphy, Tignish, P. E. I.; *Vice-Presidents*, Dr. W. B. Moore, Kentville, Dr. S. C. Murray, Albert, N. B., Dr. George F. Dewar; *Secretary*, Dr. Melvin, St. John; *Alternative*, Dr. Corston, Halifax; *Treasurer*, Dr. McLaughlin, Charlottetown.

Obituary Notes.—Dr. George W. Hall of St. Louis, Mo., died on July 7 at his home, at the age of 77 years. Dr. Hall was graduated from the Jefferson Medical College of Philadelphia, in 1852, and in 1872 accepted a chair in the Missouri Medical College, of St. Louis.

Dr. Bernard Hesse of Saginaw, Mich., died suddenly at his home on July 14, aged 74 years. Dr. Hesse was graduated from the medical department of the University of Michigan, at Ann Arbor, in 1860, and practised, from that time until the day of his death, in Saginaw. He served on the School Board for several years, and was always keenly interested in educational matters.

Dr. William Elmer of Trenton, N. J., died at Atlantic City on July 18, at the age of 68 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1864. He was at one time President of the New Jersey State Medical Association. Dr. Elmer came of a long line of physicians, five generations of whom were graduates from the University of Pennsylvania. He was the third Dr. William Elmer in successive generations.

Dr. Albert Heilbrunn, formerly of Philadelphia, died at Atlantic City on July 17, at the age of 78 years. He was a graduate of Berlin and Heidelberg Universities.

Dr. Augustus H. Wurtele died of apoplexy at Philadelphia on July 21. He was graduated from Jefferson Medical College in the class of 1893.

Dr. Charles Edward Swan of Calais, Me., said to be the oldest practising physician in the State, died at his home on July 13, following a stroke of paralysis, at the age of 86 years. Dr. Swan was graduated from the Brunswick Medical School in 1847, and had for years served as consultant on the staff of the Maine General Hospital.

Dr. John McEwen Wetmore of New York died suddenly at his home on July 21, aged 75 years. Dr. Wetmore was graduated from the College of Physicians and Surgeons in 1856, and was a consulting physician to the Hahnemann and Laura Franklin Hospitals.

Obituary.

CARLETON PHILLIPS FLINT, M.D.

New York.

Dr. Carleton P. Flint was knocked down by a recklessly driven automobile at the Seabright, N. J., railroad station on the evening of July 24, and died a few hours later of his injuries. Dr. Flint was one of the best known of the younger surgeons of New York. He was born in New England thirty-five years ago, and was graduated from Harvard Medical School in 1896. He was an attending surgeon at the Roosevelt Hospital and an instructor in the College of Physicians and Surgeons. He was a man of great promise, a careful observer, an earnest student, and a skillful operator; he also was a writer of ability and had contributed several papers of unusual value on fractures and other surgical subjects to the medical press.

Correspondence.

RECENT MEDICAL DISCUSSIONS OF THE ALCOHOLIC PROBLEM

To the Editor of The Medical Record:

Sir:—The American Society for the Study of Inebrity and Alcoholism, which was organized in 1870 in New York City, has, within the last few years, come into great prominence, and is recognized abroad, and its work is attracting increased attention. At the beginning its members were physicians actively engaged in the management and institutional care of inebriates. Later it included neurologists, physiologists, chemists, and medical men interested in the general subject of alcohol and the diseases which it causes. In 1890 the late Dr. N. S. Davis organized a society for the study of alcohol and its physiological action in medicine. A few years later this society united with the former and became an association for the study of inebriety and alcoholism. This society has been, and is, an organization of physicians, with no other object than to study the neuroses, psychoses, and action of alcohol. It is not a partisan for the promotion of any special theories or to sustain any party or organization, but simply to ascertain the facts and try and group the conclusions into some general, practical measures, that can be utilized in the study of this subject. The central fact about which this society has grouped all its studies, has been that alcohol is a poison in the broad sense, and the injuries which follow are veritable diseases. The papers and transactions of thirty-eight years have gathered about these two facts a great variety of conclusions and new views of the utmost importance. These have been published since 1876 in the *Journal of Inebriety*, the organ of the association, and have gradually educated the medical profession to recognize the whole study as a new field of physiological and psychological medicine. Recently the great temperance societies have realized that their best studies and work must be supplemented by papers and discussions from physicians. Hence medical men have been invited to take part and in some way direct their efforts in the name of science. A few years ago the W. C. T. U. at their great annual gathering began to invite physicians to address them, and other temperance societies followed, appealing to the profession for counsel and advice. Many of the great church temperance societies have placed medical men on their board, and in this and other ways sought to utilize the experience of physicians.

The members of the Society for the Study of Inebriety were nearly all members of the American Medical Association, hence it was found most convenient to hold their annual meetings at the same time and place as the last named society. For many years these meetings were small and scarcely ever numbered over 20 or 30 persons. During the last two or three years the interest has increased until large crowds, beyond the capacity of the hall to accommodate them, are now the rule rather than the exception. It is now proposed to have a distinct meeting a few days before that of the American Medical Association. A resolution was passed to appeal to the American Medical Association for a separate section on this subject.

In 1907, at Atlantic City, N. J., a lunch was projected after the manner of the gathering of the British Medical Association. Over 150 persons dined together, after which they listened to several strong speeches by leaders of the profession. The novelty of the occasion attracted a large number of persons, who became enthusiastic to continue the custom. At the late Chicago meeting a similar lunch was provided and celebrated with great enthusiasm and remarks by leading medical men. It was very evident that this will be a permanent feature of the annual gatherings in the future, and will be an occasion for educating the profession to take a broader view of the scientific study of the great alcoholic problem. As an example of the work done at the Chicago meeting a summary of the papers read will be interesting. They will all be published in the *Journal of Inebriety*, but as this journal is limited in its circulation, the scope and range of the work will not be known to the general profession.

The annual address before the society was by the president, Dr. H. O. Marcy of Boston, Mass., whose subject was: "The Temperance Movement in the South from a Medical Point of View." He indicated from statistics and studies of the mortality tables, as well as the opinions of eminent medical men, that the unsettled social condition and degeneration of the colored people was the subject of great concern, and also that all measures that increased or favored the unhygienic conditions of living produced a sense of alarm. The temperance movement spreading over the South was not based on sentiment or theory, but dated farther back to a consciousness of fear and peril to both life and property growing most rapidly where alcohol as a beverage was practically free. He characterized this movement as a cosmic consciousness of alarm, which was growing in all classes, irrespective of theory, and which materialized in efforts to overcome and prevent, by legal and other measures.

Dr. D. H. Brower of Chicago presented a paper on the "Prevalence of Alcohol as an Active and Predisposing Cause of Brain and Nervous Diseases." He asserted that all the most advanced studies in the etiology of neurotic diseases made alcohol more and more prominent, and, next to syphilis, may be considered the greatest active cause of diseases of modern civilization.

Dr. G. H. Benton of Chester, W. Va., described in detail the action of alcohol in producing autointoxication, and showed how the drink craze is reproduced and kept alive by the ferments and metabolic changes in the stomach. He showed that the beer drinker was particularly exposed to these active causes, and whatever the first cause of taking spirits might have been, its continuation was very largely due to this cause.

Dr. J. M. Aikin of Omaha, Neb., discussed the functional and organic disturbances which preceded the use of alcohol, and which apparently were covered up by the paralyzing effects of this drug. He indicated that alcohol, either as a beverage or a remedy, was most disastrous in perpetuating the pathological changes existing.

Dr. John Punton of Kansas City, Mo., declared that inebriety was a complex disease, that was curable to a very large degree by practical hygienic training in early life, particularly in relation to nutrition, elimination, and surroundings.

Dr. J. D. Mishoff of Milwaukee, Wis., discussed the problem of why spirits are taken as a beverage, and concluded that it was due to nerve exhaustion and starvation, for which alcohol was a most grateful narcotic.

The second session was opened by an address from Prof. W. S. Hall of Chicago on "Recent Researches in the Physiology of the Action of Alcohol on the Cells and Tissue." He concluded that laboratory research work from every point of view confirmed the statement that alcohol was a paralyzant and its action on the cells and tissues was corroding and destructive, both chemically and physiologically.

Dr. C. H. Hughes of St. Louis, Mo., read an elaborate paper on the "Neuropsychopathic Diathesis of Alcohol," and showed that there was unmistakable evidence that such a condition wos both inherited and acquired and was marked by an intense desire to seek relief through alcohol, irrespective of all considerations and conditions. A study of this diathesis threw much light on the mysterious neuropsychopathic diseases which often baffled medical skill.

Dr. R. H. Mettler of Chicago followed with a paper giving examples of the influence of alcohol and narcotics often taken secretly and in so-called moderation, which when removed resulted in recovery. He indicated that all obscure diseases of the brain and nervous system might have an origin from this source, and no clear diagnosis could be made unless this cause was eliminated.

Dr. G. E. Petty of Memphis, Tenn., showed that drug neurosis was increasing in this country, and that the causes were more or less tangible, particularly in toxic conditions from a great variety of sources.

Dr. E. A. Sterne of Indianapolis, Ind., compared the slow and rapid method of the withdrawal of narcotic drugs, and gave the result of his experience, describing at length the conditions for which success might be expected.

Dr. C. A. Rosenwasser of Newark, N. J., discussed the therapeutics of inebriety and the possibility of permanent restoration from appropriate treatment and exact surroundings.

Prof. G. D. Haggard of Minneapolis, Minn., urged that the medicinal action of alcohol should be tested by clinical experience in hospital and private practice, in more exact ways than at present. He deplored the bad teaching of medical colleges concerning alcohol, and thought much of the confusion at present was due to a repetition of old time theories which experience has declared untrue.

The third and last session was opened by an address from Dr. L. D. Mason of Brooklyn, N. Y., who discussed the influence of pauper inebriates on the physical and moral health of the community. He showed that misapplied charity, given to this class, all went into the pockets of the saloon man, and kept alive an enormous evil, which should be treated the same as smallpox and yellow fever. He gave elaborate statistics and quotations from authorities, showing the criminal losses to the community and tax-payer from this source.

Dr. G. Frank Lydston of Chicago read a paper on the close connection between crime and alcoholism. He pointed out that the alcoholic was a trained criminal by

reason of the paralysis of the higher mental faculties, also that his criminality was of a very low type. All this was confirmed by statistics and studies.

Dr. Arthur MacDonald of Washington, D. C., read a paper on the "Statistical Studies of Degeneracy Dating to the Use of Spirits and Drugs." These studies included the history of a large number of persons, and showed the rapid decline to extinction which followed from this entailment.

Dr. J. H. Kellogg of Battle Creek gave an address on "Malnutrition as an Active Cause for Inebriety and Other Neuroses." He showed from chemical studies and tables the degrees of poisoning and exhaustion from this source.

Dr. W. H. Waugh of Chicago gave the result of the use of gelseminine in the withdrawal of morphine, and concluded that it was one of the most reliable remedies so far found to be useful in this disease.

Dr. C. J. Douglas of Boston, Mass., described his method of treating morphinism by substituting other drugs, and supported his claim by clinical examples.

Dr. T. D. Crothers of Hartford, Conn., described the work of the International Temperance Bureau and the American branch at Boston, the object of which was to gather and tabulate all facts and statistics concerning the alcoholic problem.

The World's Temperance Centennial Congress, which met at Saratoga Springs, N. Y., from June 14 to 23, was a gathering of delegates from thirty-two different temperance organizations in this country and Europe, for a general conference and to commemorate the centennial of the formation of the first temperance society at Moreau, N. Y., a few miles from Saratoga Springs. The managers of this congress invited the Society for the Study of Inebriety to hold a meeting at the same time and place so that the leading philanthropists and temperance men might have an opportunity to hear the results of scientific study by this body. This was simply an independent meeting of the society for the presentation of papers, purely scientific, and as a contribution to the subject from the medical side.

Dr. H. O. Marcy of Boston gave the opening address, devoted to a review of the life and work of the leading medical men of the last century who have been prominent in calling attention to the dangers from the use of alcohol and urging a medical study of the subject. Beginning with Dr. Rush he mentioned a number of very prominent men who had written against this drug and did all they could to influence the profession at that time against its use. He concluded with a graphic review of the late Dr. N. S. Davis, and his work.

Dr. T. D. Crothers of Hartford, Conn., followed along the same line reviewing the temperance work of the doctors and the late Dr. J. E. Turner, who founded the first inebriate asylum in the world, and the medical reformers of a half century ago.

Dr. V. A. Ellsworth of Boston, Mass., contributed a history of the first institution for inebriates and the first efforts for medical treatment and the results. Miss Cora F. Stoddard of Boston, Mass., secretary of the Scientific Temperance Federation Bureau, described the work of the past year and the rapid accumulation of papers and statistics concerning alcohol and the future value of this bureau to all students of the subject.

Dr. J. B. Learned of Northampton, Mass., read a paper showing the influence of bad training in home and school life, resulting in degeneration and subsequent alcoholism, giving examples and opinions of educators.

The second session was addressed by Dr. W. S. Hall of Chicago on "The Teachings of the Laboratory and Research Work Concerning the Action of Alcohol," a continuation of the first paper which formed his address for the Chicago meeting. He was followed by Dr. L. D. Mason of Brooklyn, N. Y., who discussed at some length the delusions prevalent in popular lines relating to the harmlessness of moderate drinking, and pointed out by examples and experience the fatality of such opinions.

Dr. G. H. Benton of Chester, W. Va., showed that diet was very important in the treatment of inebriates and should be considered as of equal value to that of drugs and other measures used.

Dr. H. S. Drayton of Jersey City, N. J., pointed out the laws of degenerative heredity, which move with unerring uncertainty, also that a study of this phase of the subject must constitute a very practical part of all efforts to overcome the evils of alcohol.

The third session was onened by an address by Dr. C. H. Hughes of St. Louis, Mo., who gave particular emphasis to the fact that the circulation of alcohol in the blood was particularly injurious to the minute arteries of the cortex, interfering with the protoplasm, and always followed by degeneration of the cells and cell growth. He asserted that recent researches had indicated very serious injuries from this source which had not been noticed before.

Dr. J. H. Kellogg of Battle Creek gave an address showing the damage from the excess of proteids in the foods and the fermentations which followed producing irritation and exhaustion, which was very largely an exciting cause in the production of inebriety. He called attention to the statistical fact that drug and spirit taking were more incurable and difficult to treat in persons who ate large quantities of meat, and showed how it was possible that excessive proteid diet of this kind might complicate and make these disorders more incurable.

Dr. S. H. Kress of Washington, D. C., followed with a paper on "Mental Degeneracy from Alcohol." He illustrated with a history of the effects of alcohol on the South Sea Islanders and other native tribes, bringing out the fact that alcohol had a peculiar degenerative influence, not only on the individual, but on the race, and this influence extended down to future generations, continually weakening and destroying them. He urged that the same influences were at work in our present civilization eliminating the weak and the unstable with absolute certainty.

Dr. C. H. Shepard of Brooklyn, N. Y., urged that the Turkish bath was the most powerful remedy for the restoration of drink and drug victims, and that no measures would be complete without the use of this agent. He presented statistics to prove his conclusions.

The society attended in a body the unveiling of a tablet to the memory of Dr. W. J. Clark at Moreau, N. Y. An address was delivered by the Rev. Dr. Wilbur and followed by remarks by Dr. Crothers, who declared that the formation of the first temperance society at this place was a scientific work in spirit and purpose, as much as the laboratory work and researches of to-day.

At the fourth and last session Dr. J. D. Quackenbos of New York City gave an address on "The Power of Mental Suggestion in the Control of Inebriety." This was a clinical grouping of facts showing the value of psychopathic treatment and the power of suggestion in the control of the drink impulse and a plea that the profession take it up and make a practical test of it.

Dr. D. Paulson of Hinsdale, Ill., considered in some detail the means and methods of the application of mental suggestions and the correction of surroundings and the physical influences essential in the successful treatment of inebriates. He claimed that inebriety was thoroughly curable in proper surroundings and by the use of means and measures which experience had found useful.

Dr. Crothers of Hartford, Conn., concluded the session by pointing out some of the conditions represented by the term "New Thought" in relation to mental life, and showed their scientific relation to psychopathic and physical treatment.

The canteen question was the subject of a special session Monday afternoon. Dr. J. W. Grosvenor of Buffalo, N. Y., gave an exhaustive review and history of the arguments and reasons which had brought the question of the sale of spirits and light wines at the canteen into controversy. He showed the reasons for the repeal of the use of all forms of spirits in the canteens, and gave statistical tables and opinions of authorities, both in favor and against spirits in the canteen. He reviewed the controversy which had grown up about this subject and indicated the facts which were so far sustained by all the evidence. He was followed by Dr. Crothers of Hartford, Conn., who reviewed the researches of Kraeplin and other authorities concerning the effect of small amounts of alcohol on the brain and nerve activities, and gave the conclusions of laboratory researches concerning the peril and injury from these agents to the efficiency and vigor of persons. A number of very frank inquiries followed these papers and the discussions were marked by great fairness and candor.

These two meetings of the association attracted enthusiastic audiences and were listened to with great interest. The last meeting was historical as the first attempt of medical men to discuss the alcoholic problem exclusively from its scientific side before an audience of laymen. The papers were prominent as studies of facts, and the conclusions following were singularly free from dogmatism and theorizing. It was evident that a new step forward had begun in the temperance work in which medical men were to be called on to take an active part, and that hereafter no gathering of laymen to discuss this subject could be complete without the influence of physicians to give assistance and direction to their studies. It is also very evident that both the profession and laymen are gradually recognizing that there is an undiscovered field where the causes of the great alcoholic problem can be studied, known and prevented, and that hereafter all the great work of reform must be directed by trained medical men, and in some way guided by their researches.

The International Alcoholic Congress, which occupied

so large a place in the history of reforms last year, is to be repeated in London in 1909, and work for an immense gathering is already being projected. This will be under the auspices of the British Government. The Duke of Connaught will be Honorary President.

Official delegates, principally medical men, will be sent from all the civilized countries in the world, the central purpose of which will be to discuss the hygienic, social, and scientific problems connected with the alcoholic question. This will be thoroughly scientific and statistical and will be supplemented by studies of the reform work in societies, churches, and other movements. This will bring together a great army of laymen and reformers with all their plans and projects and they will have full opportunity to present and discuss in separate sections. The event will be epoch-making and indicate the growing interest in the evils that come from alcohol as a beverage, which is being recognized in all countries of the world.

T. D. Crothers, M.D.

Hartford, Conn.

OUR LONDON LETTER.

(From Our Special Correspondent.)

CAVENDISH LECTURE ON TUBERCULOSIS, ETIOLOGY, RECENT RESEARCHES—GRADUATED WORK AT FRIMLEY SANATORIUM—LONDON HOSPITAL—ROYAL COLLEGE OF SURGEONS, THE POLL ON THE ADMISSION OF WOMEN.

London, July 10, 1908.

The Cavendish lecture for this year was delivered at the West London Medico-Chirurgical Society on the 26th ult. by Professor Sir William Whitla of Belfast. He took for his subject the "Etiology of Pulmonary Tuberculosis." After referring to the question of differences between human and bovine tubercle and accepting the conclusions of the great majority of recent investigators that they are identical, he passed on to the etiology of phthisis. The study of this narrows itself into the consideration of the two obviously probable routes of infection—the respiratory and the intestinal surfaces. After the discovery of the bacillus and its constant presence in the sputum, and the knowledge from history that the lungs were the seat of the disease in almost all cases, it was naturally held that pulmonary tuberculosis must be a primary disease, and this view is still generally accepted. The lecturer, however, went on to show that, although phthisis may be produced by inhalation, many facts obtained by recent experiments go to prove that the intestinal route plays a far more important part in the production of human phthisis than has heretofore been recognized. The inhalation theory is based on the results of pulmonary anthracosis, experimental and pathological, and also on the successful infection of animals by causing them to inhale an atmosphere laden with bacilli. Hundreds of animals after breathing such an atmosphere have contracted the disease and clinical experience shows that persons become infected in the environment of patients. But late experiments have shifted the question of entrance. Calmette and Guerin's work in this direction seemed so startling and the conclusions from them so vital that Dr. Whitla, in conjunction with Professor Symmers, undertook a series of experiments upon guinea-pigs, with a view of testing them. To give a birdseye view of the results the lecturer exhibited some splendid specimens permanently mounted in gelatin. To test the power of the pulmonary capillaries to filter out fine particles of carbon circulating in the blood, a mixture of China ink and water was injected into the large vein in a rabbit's ear. The lung of the animal, killed an hour afterwards, was highly charged with carbon particles, in obvious contrast with that of a control mounted beside it. Another specimen was from an adult guinea-pig, killed, after feeding for four days with an emulsion of ink, through a rubber tube in a way to prevent possible soiling of the mouth, pharynx, etc. This experiment, repeated twenty times, gave striking results. The lungs were blackened in the upper lobes and the margins of the lower lobes within eight to twenty-four hours. In some other experiments the lungs were infiltrated with the carbon particles after injections into the peritoneal cavity, but the abdominal lymphatics remained free. Clearly the carbon particles easily obtained entrance through the intestinal epithelial surface, reached the lymphatic paths, passed through the mesenteric glands, either enclosed in phagocytes or free, and so into the thoracic duct and venous circulation, to be at last arrested in the pulmonary capillaries.

Vansteenberghe and Grysez found a great difference in the result with young guinea-pigs. In them the carbon particles were arrested in the mesenteric glands. Sir William Whitla and his colleague, Symmers, accordingly tested this. Dense blackening of the abdominal lymphatics was found twenty hours after injecting a young guinea-pig. The carbon had also reached the thorax through the lymph channels of the diaphragm, which was jet black throughout; also the right costal pleura was black, but the lungs were quite free. In ordinary feeding experiments of young animals the lungs remained free in contrast with the dense blackness produced in full-grown animals. The lecturer recalled that Calmette and Guerin concluded from other researches that air-borne bacilli could not penetrate the pulmonary parenchyma, and Von Behring, at the Cassel Congress, 1903, advanced the then startling doctrine that phthisis in the adult was not produced *via* the air passages, but is always the result of a long past absorption from the intestine in childhood. The main question for the practitioner is whether the bacilli pass through the intestinal mucosa like the carbon particles. This the lecturer asserted could no longer be denied, as it had been proved by experiments too numerous to mention. The exhaustive researches of Calmette, Guerin, Breton, and others give a constant result. Injections of emulsion of living tubercle bacilli produced deposits in the mesenteric glands and other viscera. When the animals survived thirty days the lungs were always studded with caseous particles and the bronchial and tracheal glands were affected. If they were allowed to live for from fifty to sixty days the deep cervical glands were almost always tuberculous. This is of the utmost importance in view of the usually accepted opinion that affection of these glands points to entrance through the mouth, tonsils, or pharynx. That this is not the case has been shown by most careful experiment by Calmette and others. Guinea-pigs killed ten days after bacilli had been introduced into the stomach by the tube were found to have the entire lymphatic system infected, and healthy animals inoculated with the substance of the inguinal glands died from extensive generalized tuberculosis.

Sir William Whitla then gave some account of two outbreaks of tuberculosis he had observed in an isolated charity school of 150 children. These he had traced to the milk supply. In looking back over about thirty years in connection with this institution he declared himself convinced that other outbreaks were due to the same cause and he has little doubt that soon many such cases will be recorded. From clinical observation and experimental results, he felt convinced that in regard to phthisis, dosage is everything. The bacillus must be ubiquitous, considering the number of tuberculous cattle and phthisical patients. Natural resistance, hereditary or other, affords protection, but when the dosage is too heavy probably no human being can escape.

Admitting that a great proportion of the myriads of bacilli must be dead, it cannot be denied that everyone must draw them into the air passages and probably take some in most of his food. But for some way in which they are dealt with in the organism, phagocytic or other, the lecturer thought few, if any, would be left to study or discuss the problems of tuberculosis. As soon as any part gets its vital resistance lowered by injury or otherwise, arrest of phagocytosis ensues. As instances familiar to all, tuberculous testicle and spinal caries following a blow without any break of surface were mentioned, also phthisis following pneumococcal or streptococcal pleurisies. The conclusion reached was that probably phthisis will be recognized in the immense majority of cases as caused by the entrance of germs through the intestinal mucosa without the necessity of any break of its surface.

The Brompton Hospital Sanatorium at Frimley was visited on Saturday by a large party interested in the system which has been at work now for four years. It is the method of graduated work which has been carried out in this sanatorium. Seven grades of exercise and work are in use under the supervision of Dr. Paterson, the superintendent. The male patients pass from one grade to another until at last they can do a navvy's work. The women's grade corresponding to this is scrubbing indoors. When a man is thought fit to be discharged, he is set to work at his trade, if he has one, for six hours a day for three weeks, to bring his muscles into training again. Of patients who have been sent out as recovered to their former employment (policemen, blacksmiths, dock and other laborers) 80 per cent. are reported to be in full work. The treatment is being extended to the King's Sanatorium and the National Sanatorium at Benenden, as well as to the Ventnor Hospital for Consumptives. For per-

sons of limited means, who can afford to pay something, twenty beds are to be set apart.

On Monday the quinquennial appeal for the London Hospital—the largest of all—was opened at the Mansion House, when the Lord Mayor entertained several hundred guests at dinner. Lord Rothschild proposed the toast of "Success to the London Hospital" and told how, two hundred years ago, some "adventurous spirits, among whom was the great and reverend John Wesley," met in a tavern and decided to furnish a house on the site now occupied by the London Hospital. They had only one shilling in hand when the work was completed, but somehow it went on and the house grew into four and has grown ever since. The hospital is now nearly complete for its work and requires £400,000 for its upkeep during the next five years, as 1,500,000 patients will have to be ministered to, according to the estimated growth of the population. The assured income of the hospital is about £20,000, the expenditure £100,000. For the balance of £80,000 voluntary contributions are needed.

Yesterday afternoon, at a meeting of the Council of the Royal College of Surgeons, the result of the poll regarding the admission of women was announced. There was a majority of 415 against their admission to the membership and of 1,182 against their admission to the Fellowship.

The votes of Fellows taken separately gave a majority of 288 in favor of admitting to membership and of 34 to the Fellowship.

The votes of members taken separately were against in both cases—a majority of 703 against as to membership and 1,216 as to Fellowship. Out of the 1,373 Fellows 1,043 voted and out of about 13,800 members 8,543 voted. The subject will be considered by the Council in October.

Mr. Henry Morris was reelected president, Sir Watson Cheyne and Mr. Pearce Gould vice-presidents for the ensuing year.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

ANTAGONISTIC ACTION OF DRUGS—STONE IN THE BLADDER—A FOREIGN BODY IN THE BLADDER REMOVED BY A SOLVENT—HEMANGIOMA CAVERNOSUM OF THE LARYNX.

VIENNA, June 1, 1908.

A FEW days ago Professor Horst-Meyer spoke before the Physicians' Society on "The Antagonisms of Poisons." He said that such antagonism may be a direct chemical one between the toxic substances, or an indirect one caused by opposing physiological action. In the study of this relation experiments on animals are necessary, because the mere chemical composition of the poisons can only suggest the possible antagonism of the first kind mentioned above. In the direct chemical antagonism the poison and its antagonist combine together and the result is an indifferent substance. In the second type of antagonism the poisons do not affect each other, but influence an organ in such a way that the results of this influence oppose each other. For example, atropine has a paralyzing effect upon smooth muscle fibers and upon the heart, while pilocarpine stimulates the same structures. For the most case the inhibitory effect of the poison is more distinctly felt, yet often enough the stimulating action appears quicker. The explanation of the result produced is especially difficult when the central nervous system is the field of the antagonizing influences; examples of such action are seen in the inhibitory effect of morphine, the stimulating effect of atropine, the inhibitory influence of chloral hydrate and of alcohol, and the stimulating effect of caffeine, morphine, and picrotoxin. There are likewise drugs that lower or raise the temperature in opposition to each other's action. Not explained are the processes that take place when a motor neuron or a motor field receives impulses of opposing character from two different sources, one of them being inhibitory in character while the other is of stimulating nature. In still a third type of antagonism the opposing principles affect organs that are physiologically pitted against each other. The muscles, the vessels, the glands are subject to the influence of the vegetative automatic system of nervous control, being at the same time open to the effect of inhibitory and of stimulating action of the central nervous system. The vegetative system of nervous control consists of the following elements: (1) Nerve fibers that originate from the middle and from the hind brain and run some distance with the oculomotor, the facial, the glossopharyngeal, and the vagus nerves; (2) nerve fibers that originate from the spinal cord up to the fourth lumbar nerve and pass to the sympathetic paths; (3) fibers of the pelvic nerves which spring from the sacral prolongation of the spinal cord and supply the colon, the urinary bladder, and the genital organs. The sympathetic vegetative system supplies the whole body and has for its antagonists the two other systems of nervous control. The cranial and the sacral nerves of automatic action are stimulated as far as their end organs are concerned by pilocarpine and the like drugs, and are inhibited by the atropine group; the sympathetic system, on the other hand, is not influenced by these drugs.

The drugs that act upon the sympathetic system consist of such substances as adrenalin and cocaine which stimulate it, and of drugs like codeine which paralyze or inhibit it. An organ which is supplied by two antagonistic groups of nerve cells, that is, by the cranial and sacral nerves on the one hand, and by the sympathetic fibers on the other, may be influenced in various opposing manners by the different poisonous elements; for example, its vessels may be contracted by the action of pilocarpine and may tend to be dilated by the influence of cocaine or adrenalin, because of the different degree of influence exerted by these drugs upon the structures affected by them. There exists probably an opposing action between the various secretions, as for example between those of the pancreas and those of the adrenal body upon the glycogenic function of the liver, the antagonistic effects of the medulla and the cortex of the adrenal gland and of the thyroid and the genital glands upon metabolism, but we know as little about this phase of their activity as of the principles responsible for it.

Some interesting cases of urinary stone have been observed by Dr. Alexius Avarffy of the First Female Clinic. In the first case the stone was formed in the bladder by deposits about a hairpin. The latter became non-movable, a concretion of the size of a hen's egg formed about it, and finally began to press upon the wall of the bladder. In response to the injury there appeared an inflammatory reaction with the formation of granulation tissues, which buried the free ends of the foreign body and produced a necrosis of a portion of the bladder wall by pressure upon the blood-vessels. A colpocystostomy was carried out, the stone being a fixed one, and a vesicovaginal fistula resulted from the operation. Three further operations were necessary to repair this lesion. The woman meanwhile had become pregnant, and the labor as well as the puerperium passed without any disturbance. In the second case, the salts were not deposited about a foreign body, but were precipitated into a bladder diverticulum. In this case, likewise, a local inflammatory reaction resulted, the products of the inflammation serving to fix the stone still more firmly in the confined space it occupied. Apparently the patient was suffering from a uric acid diathesis, for a stone the size of a hazelnut was discharged spontaneously by the vagina. A vesicovaginal incision was made in this case also, and a fistula leading into the cervix was discovered occupying the spot of necrosis produced by the pressure of the stone. The anterior lip of the vaginal portion of the cervix was excised as far as the fistula, the stone was freed and removed through the wound, which was then closed. Healing by primary intention resulted and the woman left the clinic on the twentieth day, cured of her complaint. In the third case the stone formed in a cloaca, being deposited in a small pocket which resulted from a previous operation upon the genital organs. Both rectum and bladder opened into this pocket. The rectovaginal fistula was closed after prolonged irrigations had been employed, while the vesicovaginal fistula was left patent for the time being. Two further operations completed the cure. Of great interest in this case is the fact that the infection with the colon bacillus which was present about the opening of the bladder did not ascend to the kidney in the twelve years of its existence.

Dr. Lenk, of Professor Hochenegg's clinic, had occasion to remove a foreign body, a stearin taper, from the bladder and devised an ingenious procedure for the operation. The patient was a married man, fifty-six years old, who had masturbated for many years, introducing pencils, penholders, brush handles, etc., into his urethra. On one occasion he made use of a stearin taper for this purpose and it inadvertently slipped into the bladder. A few weeks later the man appeared at the clinic with marked hematuria and the signs of a well developed cystitis produced by the presence of the foreign body. A cystoscopic examination disclosed an ulcerative cystitis of a severe grade and the foreign body all twisted and incrusted with salts floating in the fluid used for cystoscopy. It seemed impossible to remove it by means of an operating cystoscope or by a lithotribe, for the incrustations upon it would certainly have caused much damage. "Sectio alta" was, too, a dangerous procedure because of the severe cystitis. Lenk decided to dissolve it by means of benzine. He experimented upon himself and found that the healthy bladder could retain about fifty cubic centimeters of benzine with-

out being unduly irritated; care was to be taken, however, not to bring the benzine in contact with the posterior parts, for very marked tenesmus resulted on such contact. Moreover, it could be expected that the damaged mucous membrane of the patient's bladder would prove much more sensitive to the action of the irritant. An attempt to use benzine showed that this expectation was a correct one and Lenk decided upon a somewhat different procedure. The bladder was filled with 120 cc. of sterile water in which the piece of taper floated. Then fifty or sixty c.c. of benzine were introduced, it being expected that the benzine would rise to the surface of the water and there act upon the taper. This method was preferred because the water distended the bladder and allowed the benzine to act thoroughly upon the foreign body, and at the same time but a very small part of the bladder wall and a comparatively healthy one came in contact with the irritating solvent. Especial protection from this action was obtained for the bladder fundus which suffered most from the inflammatory process and which now had a layer of water between it and the benzine. The solvent was allowed to act for about twenty minutes, was then allowed to escape, and the bladder was thoroughly irrigated with water. Thus it was possible to remove the foreign body slowly without causing too much unnecessary pain to the patient. The taper stearin gradually broke up into small pieces because of the solvent action of benzine and these were passed spontaneously. Five injections of the solvent, which was allowed to act about twenty minutes each time, were sufficient to free the bladder completely of the stearin particles. The wick was then easily removed by means of a lithotribe.

Dr. Hugo Zwillinger had recently an interesting case of cavernous hemangioma of the lower pharynx under observation. The patient was twenty-two years old and showed a dark red to bluish black tumor in the right pyriform fossa. Only the upper part of the ary-epiglottic fold was left free by the growth, which covered up a part of the false vocal cord and narrowed the upper portion of the rima glottidis. The surface of the tumor appeared uneven and nodular. The mass stretched in the direction of the right vallecula behind the epiglottis toward the root of the tongue and covered the right pharyngoepiglottic fold. It was attached by a broad surface to a lappet of tissue, originating from under the right tonsil, filled out the right vallecula and ended at the root of the tongue. Digital examination also showed that the tumor surface was uneven; the mass, moreover, was soft and somewhat compressible. The diagnosis was hemangioma cavernosum, a condition very rarely met with on this site. Mikulicz could report only two cases of this affection up to 1889.

Progress of Medical Science.

New York Medical Journal, July 18, 1908.

Dermoid Tumor of the Conjunctiva.—Eleven instances of this rare lesion have been recorded in the last 43 years. An additional case is contributed by M. J. Levitt, whose patient was a male child of five weeks. The growth on the eye measured 8 or 9 mm. in length, 6 to 7 mm. in width, and 2 to 3 mm. in thickness. It was located on the sclerocorneal junction, more on the cornea, was hard in consistency, and free from inflammation, while the rest of the globus was normal. Otherwise the child was normal. Immediate removal was advised but deferred by the mother. Levitt says that such growths in this situation are always congenital, benign in nature, and usually connected with some other malformation or deficient development of the eyelid or other part of the face, such as coloboma or hare-lip. The usual seat of the tumor is at the sclerocorneal junction, but it may occur at any other place of the conjunctiva. The size varies from that of a split pea to that of a cherry. Histologically, these tumors contain all the elements of skin and its appendages, such as hair follicles, sebaceous and sweat glands. In consistence they are either hard or soft, according to the amount of fatty tissue they contain. Dermoids are supposed in general to be due to amniotic adhesions or to invagination of the ectoderm.

A New Corset for Gastroptosis.—The special feature of the corset devised by A. Bassler is its concave abdomen, hollowed in its depth according to the extent of prolapse of the organ or organs within and the bulk of the abdomen, otherwise it is a well fitting, stylish, made-to-order corset, not any larger in the circumference at the waist line than the normal measurement would be, with a contraction transversely to shape it in at the waist, and a corresponding fullness in the costal region to allow for the sustained organs. The concavity is below the umbilicus and at the sides, between that and the anterior superior spines of the ilia down to Poupart's ligament. This feature is brought about by a series of corset steels, which have been bent, then tempered, and placed in the corset in the manner shown in the illustration in the original paper. The corset here described does not depend upon any extreme degree of snug fitting about the hips and lower abdomen to squeeze the underlying tissues and thus hold up the viscera. Even with the women standing the lower part of the corset does not have the extreme close fit as the previously mentioned garment with the women lying down. The entire hand can be readily slipped between it and the abdomen, and still the support factor is accomplished. Nor is it necessary to loosen the lower string of the corset to put it on, as is requisite with the other garment; the corset when once adjusted is taken off and put on without any widening change, and thus its degree of support is not changing day by day, as is the case when the strings are constantly being adjusted. It has not been found necessary to pad the lower edge of the corset so as to relieve point pressure on the anterior superior spines of the ilia or elsewhere. Full directions for application of the corset are given in the original paper.

Syphilis Extragenitally Acquired in Early Childhood.—The various ways in which young children become infected innocently by the virus of syphilis are enumerated by F. C. Knowles. He mentions particularly, parturition, circumcision, vaccination, breast feeding, hand feeding, fondling household utensils, toilet articles, unsterilized surgical, dental, and electrical appliances, careless and unclean methods of dressing wounds, and removal of foreign bodies. Illustrative cases are given under each heading. Nothing new is presented.

Journal of the American Medical Association, July 18, 1908.

Disease of the Cerebral Vessels.—W. A. Jones reports three cases, two of them with post-mortem examination, of brain disease more or less suggestive of focal basal or cerebellar lesions. In the two cases examined post-mortem, there was marked thickening of the arteries at the base of the brain, irregular with multiple aneurysms in one, and uniform in the other, with aneurysms of both vertebral arteries at the level of the first cervical nerve. The cause of death in the first of these cases was obstruction of the circulation in the cerebellum and brain-stem; in the other, the direct pathologic lesion causing death, which occurred with rapidly increasing paralysis and rigidity, was not evident, but the most pronounced post-mortem finding, other than the condition of the vessels, was edema.

Cerebral Inhibition and Motor Function.—H. A. Tomlinson reports cases and reviews the physiological facts that seem to him to show that extreme incoordination of voluntary movement, and even palsy, may result from simple cerebral inhibition in cases in which there are no symptoms of organic disease of the nervous system other than psychic ones. The complexity of function is such in the human brain that under certain conditions there may be disintegration of function and disassociation of the elements of complex motor activities, without lesion or morphological change in the histologic elements of the cortex of the brain. In new-born infants he had observed that when the regular order and sequence of the afferent impulses in a complex reflex is disturbed or incomplete, the efferent impulses are inhibited, and then the reflex is modified. From observations of the insane, he finds that the progress of degeneration in dementia brings about a similar state; so that as the capacity for relation, coordination, and direction are lost, inhibition becomes dominant. Thus we have various degrees of inhibition ranging from incoordination to palsy, usually first in the functions of prehension and locomotion, and next in the acts of deglutition and articulation. The three cases reported are chosen as showing the varying degrees in the development of inhibition according to the extent of the primary defect in the nervous organization, and the advance in the progress of dementia. He locates the defect of function in such cases as most probably in the cortex of the middle portion of the frontal lobes, anterior to the precentral fissure, the region which is first to atrophy in dementia and is least well developed in the originally defective. In Tomlinson's experience, inhibition and incoordination occur only in those cases in which the degeneration is primary and begins during adolescence. In such individuals the higher functions of the brain are imperfectly developed, and consequently, whatever lowers vitality may put these functions in abeyance and inhibition becomes dominant, just as in the normal individual unusual and untoward conditions may operate to produce the same result in the undeveloped and inexperienced.

Fasting in Typhoid Fever.—R. M. Harbin says the

battleground of treatment of typhoid fever lies in the gastrointestinal tract: any vital organs containing pathognomic lesions of an infectious disease need rest, and our aim should be to nourish the patient without increasing saprophytosis. The excessive nitrogenous waste in typhoid fever is not due, he holds, to the typhoid toxin, but probably to mixed infections, and emaciation occurs independently of the amount of food taken and results more rapidly from toxemia than from lack of nourishment. Therapeutic fasting allows an uncomplicated typhoid infection to pursue a normally mild course without any mixed infection, by reducing the bacterial content of the intestines. It is the severe and sthenic cases that are especially amenable to this treatment. In such cases fasting should be prescribed for from one to three days, though it is rarely advisable to continue it through the third day, as the severe symptoms are usually relieved by that time. In other than sthenic cases it is not often necessary. If pneumonia intervene, more liberal diet should be allowed. After fasting for from twenty-four to forty-eight hours, a very restricted diet of broths, etc., in prescribed amounts should be given. Harbin does not favor a milk diet, as no one can tell that it will not form a curd, which is worse than solid food. It is less liable to do so when diluted with from two to five parts of broths, hot water, etc., and may then be valuable. Gelatin he considers a valuable adjuvant in the dietary of typhoid; it adds to the relish of the various liquids, lessens the nitrogenous waste and prevents hemorrhage. He would use it as a routine in all cases, though in very aggravated diarrheic cases, in which it is not well tolerated, only in small amounts on alternate days. Fasting and a restricted diet greatly enhance the effect of hydrotherapy and frequently render the use of antipyretic measures needless. In the series of cases which form the basis of the paper, the low mortality (4.7 per cent. and only 3.4 per cent. in 144 whites) is ascribed largely to the dietic management, though many had very inefficient nursing.

Migraine an Occupation Neurosis.—G. L. Walton argues that the common type of migraine, occurring mainly in early life, is an occupation neurosis, and he rather questions the pain being altogether intracranial, a doubt emphasized by the recent observations of Cushing of the non-sensitiveness of the dura, the part to which, perhaps, more than any other, the pain of migraine has been attributed. He cites here, as illustrating this point, the muscular pain experienced in the back of the neck and "base of the brain" after long-continued eyework, and which is relieved by discontinuance of the work. In migraine there are involved: (1) the visual centers; (2) the centers of accommodation (centers of divergence and convergence in the frontal region); (3) the intrinsic and extrinsic muscles of the globe, and (4) the muscles outside the orbit which are called into play in the effort required for accurate vision, principally the corrugator supercilii and occipitofrontalis, but also the muscles inserted in the occipital region, which serve to steady the head. Walton points out the resemblances between the symptomatology of certain occupation neuroses and migraine and the fact that they both occur in the same class of neurotic and sensitively organized individuals, as supporting his theory, and the paroxysmal pain in some forms of occupation neurosis strongly suggests that of migraine. Walton does not recognize the vasomotor theory of migraine as valid because the vascular symptoms on which it is based are neither constant nor primary, and furthermore, there is no necessary connection between dilatation and contraction of blood vessels and pain. The vomiting is not easily accounted for by the occupation neurosis theory or any other, but Walton considers it probably not one of the essential features, but rather an indirect result appearing generally only in the young and at the height of the paroxysm, representing rather a protective effort on the part of Nature, through producing general and special relaxation. The fact that relief often follows vomiting bears out this idea. His conclusion is that migraine is an occupation neurosis resulting, in individuals of neurotic heredity, from overuse, or use under the handicap of refractive error, of the parts (muscular as well as nervous) concerned in vision.

Hemorrhage into the Ventricles.—Ten cases bearing on the question of the correctness of the assertion of Dejerine, Strümpell, Brissaud and Leube, that convulsions and rigidity in apoplectic hemiplegia point to the rupture of the hemorrhage into the ventricles, and also on the possibility of stimulation of the axons of the upper motor neurons when they are separated from their pericaryons, are reported by A. R. Allen, who summarizes his conclusions substantially as follows: (1) Ventricular inundation in cerebral hemorrhage has no etiologic bearing on the convulsions or rigidity. (2) Tentatively, and basing his opinion on the ten cases, he concludes that the convulsions and rigidity in apoplectiform hemiplegia are frequently due to involvement of the optic thalamus or corticothalamic sensory fibers, provided, of course, that enough of the posterior limb of the internal capsule remained intact to convey the motor impulses. (3) Convulsions and rigidity in apoplectiform hemiplegia may be caused by a sudden or rapid increase of intracranial pressure from cerebral hemorrhage, even if the thalamus and corticothalamic sensory fibers are uninvolved. In this case, also, there must be a sufficient portion of the internal capsule left uninjured to convey the motor impulses to the parts concerned. (4) It is altogether unlikely that pressure or chemical change acting on the motor axons of the centrum or internal capsule—these axons having been severed from their pericaryons by the hemorrhage—could exert a sufficient stimulating action to cause convulsions or rigidity.

The Lancet, July 11, 1908.

The Necessity for Removal of the Appendix after Perityphlitic Abscess.—W. H. Battle closes a statistical and somewhat polemic article with the following statements: The treatment of perityphlitic abscess is most safely carried out in two stages: first stage, evacuation of pus and drainage; second stage, removal of the appendix. The statements of those who held that the appendix is obliterated by suppuration around it are erroneous; it is never obliterated but remains the subject of gross disease which in many instances (20 out of 70) gives rise to a return of symptoms within a short period after the closure of the abscess. The lesions found in those cases in which the appendix has been removed for a return of symptoms do not differ in their character from those found when it has been removed as a matter of routine without waiting for symptoms. Compared with a series of appendices removed for recurring attacks, without evidence of suppuration, the lesions found after removal following abscess are more gross and give fewer instances of apparent recovery from disease. Removal of the appendix after closure of the abscess is a safe procedure, and is not followed by any weakness of the abdominal wall if done in the way suggested. Moreover, operation at an early date after closure of the abscess enables the surgeon to treat dangerous adhesions and deal with any pelvic disease which may complicate the condition.

Sarcomatosis of the Lymphatic Glands.—One case is described in great detail by W. K. Hunter, whose patient was a man 38 years old—miner, who died after an illness of about fourteen months. For a period of one year the symptoms were entirely those of Hodgkin's disease, though the glandular involvement was less widespread and more definitely confined to the cervical region than is customary in that malady. Nothing suggested that the morbid process was extending through the gland capsules to the circumglandular tissues as was proved to be the case at autopsy. Moreover there was considerable initial improvement from the use of arsenic. The author says that there are two distinct pathological conditions included under the name Hodgkin's disease. In the one (leukemia) type the histological structure of the enlarged gland is exactly the same as in lymphatic leukemia—*i.e.* there is a "hyperplasia" of the lymphoid elements of the gland. Such cases might therefore be best regarded as cases of lymphatic leukemia without increase of lymphocytes in the blood. In the other type (fibrous type) the change affects the reticulum of the gland, and as the gland becomes more and more fibrous, the lymphoid elements become less conspicuous, and may ultimately almost entirely disappear. The process is, therefore, not a hyperplasia of the lymphoid elements as in the first type, but an atrophy of these, with a hyperplasia of what are probably stroma cells (large cells with irregular ragged cell-body composed of granular protoplasm and with a large, sharply outlined vesicular nucleus, sometimes round but more often kidney shaped). It is probable that it is only in the former or leukemia type that the glandular enlargement takes on a sarcomatous change. The case recorded by the author was not a lympho-, but a large-celled, sarcomatosis.

Premonitory Signs of Arteriosclerosis.—A. S. Gubb notes that the initial manifestations of this affection vary according to the region in which its impact chances to fall, kidney, brain, heart, liver, etc. The tendency thereto is notably influenced by heredity although acquired by certain habits of life. We may have early migraine, epistaxis, baldness, etc. Constitutional symptoms comprise diminished mentality, energy for work, and power of concentration. Tendency to fatigue is shown by drawn features and psychical depression. Small amounts of tobacco and alcohol render the patient morbidly irritative. Irritability of temper is common. Judgment is impaired and self-control lessened. Headaches are frequent. Sensory disturbances in one form or another are fairly

common, such as neuralgia, tingling, numbness, slight paresis of the limbs with or without pain. Genuine insomnia is rare, though sleep is disturbed. Capiello has called attention to a peculiar sensation in the palm of the hand—a tingling along the palmar arch—when the radial artery is compressed sufficiently to arrest pulsation. A simple way of determining the existence of general arteriosclerosis is the estimation of the "stability" of the pulse. Under normal conditions the pulse-rate is eight or ten per minute higher in the erect than in the recumbent position, and when observation shows that such is not the case we may infer that the blood-pressure is markedly above normal, while if the ratio be reversed it may be taken as proved that not only is the arterial pressure unduly high but that arteriosclerosis has reached the stage of giving rise to definite organic disease, an assumption which is confirmed should we find that the heart apex is displaced to the left. Exaggerated arterial tension with a small, hard, thready but regular pulse is a recognized sign of confirmed arteriosclerosis, but in minor degrees it also constitutes an early premonitory sign; indeed, some weighty authorities believe that actual changes in the arterial walls are preceded by prolonged exposure to the ill-effects of persistent high pressure, what Huchard calls the presclerous period, such hypertension being due to spasmodic contraction of the arterioles probably dependent on toxic irritation of the vasomotor system. High arterial tension, it is true, is commonly associated with chronic renal lesions, but the presence of the latter by no means excludes the possibility of the mischief being due to arteriosclerosis; indeed, the renal lesion may be, and often is, due to local arteriosclerosis. When in addition to an abnormally high blood pressure we get some of the other signs just mentioned there is a strong presumption in favor of the existence of arteriosclerosis.

British Medical Journal, July 1, 1908.

Tincture of Eucalyptus in Hemorrhage.—A. Todd-White calls attention to the value of this remedy in cases of hemorrhage. He was sent for to see a patient who had a tooth extracted three days before, and had had persistent hemorrhage from the socket. The usual remedies were applied without avail. On the third day tincture of eucalyptus was applied and the hemorrhage almost immediately ceased. The next day the patient's brother cut his foot and the hemorrhage was profuse. Having some of the eucalyptus left he applied it to the wound, and the hemorrhage immediately stopped. Later the author was asked to see a case in which persistent hemorrhage followed the application of a leech to the gum. The usual remedies—alum, tr. ferri perchlor., ice, etc.—were tried unsuccessfully for twelve hours. He applied tincture of eucalyptus, and the hemorrhage ceased within five minutes and did not return. It is most useful as a dressing on lint after circumcision or other minor operations. He is of opinion that the internal use of calcium chloride combined with the external application of tincture of eucalyptus will stop any form of hemorrhage.

Tetany in the Adult.—Two cases are recorded by J. A. Gibb. Case 1 was that of a woman of 52 years who was said to have fainted. The author found her with the usual symptoms, the convulsions being a marked feature and yielding to the hypodermic use of morphine and atropine. The patient was seen daily for a week and gradually improved, but at the end of that time relapsed, had fresh seizures, and died. Case 2 was that of a woman over 60 years and addicted to alcohol. She had marked dilatation of the stomach, and her convulsive seizures were similar to those in case 1, except that she did not lose consciousness. A fatal result ensued in 48 hours. The probable cause of tetany in adults is a toxin absorbed from the alimentary canal. Some quotations are made from recent literature on the subject.

Congenital Narrowness of the Pyloric Orifice a Cause of Chronic Gastric Disease in the Adult.—Twelve cases are summarized by A. E. Maryland. His general conclusions are thus stated: (1) There exists an abnormal condition of the pyloric aperture, probably of congenital origin, which consists in an undue narrowing of the orifice, varying anything between 2 and 10 or 12 mm. (2) The condition is more frequently met with in women than in men, and the age at which the symptoms first appear depends upon the narrowness of the aperture and the general physical or constitutional condition of the patient. (3) The narrowing leads to a more or less chronic condition of indigestion, manifested in various forms and often mistaken for chronic ulceration or chronic gastric catarrh: that in the early stages relief is afforded by careful and strict attention to diet, but that any attempt to return to normal feeding causes a recrudescence of indigestion. The attacks of gastric discomfort are at first separated by considerable intervals, but these lessen in length as time goes on. (4) When the patient is advanced in life and shows marked general debility operation will prove of doubtful value. (5) Barring such considerations as those mentioned in (3), pyloroplasty or Finney's operation—preferably the former—should be practised.

The Etiology of Pulmonary Tuberculosis.—In the Cavendish Lecture for 1908, Sir W. Whitla traverses the field of recent investigations, touching on the salient points and summarizing the conclusions. As to the question of the identity of the human and bovine bacillus he says that a survey of the general results carries the conviction that in most if not in all cases the success or failure of experiments to settle the question is strongly a question of dosage, though Koch's followers claim that large doses constitute a violent breach of the natural powers of resistance of the animal. But it is evident that this is but giving the question away by stating in another manner that the tissues of the ox show a greater resistance to human than to bovine tubercle, a fact conceded by all authorities—the resistance breaks down in the presence of a large dose. In conclusion the author suggests that while we are hardly justified in assuming that phthisis never occurs from the inhalation of dried sputum-dust or from the breathing of the spray injected in the act of coughing, it appears to be conclusively proven that the alimentary tract is a frequent portal of entry for the tubercle bacillus, which is able to pass through the intact mucous membrane of the bowel without producing any local lesion at the point of entrance; that this event is especially frequent in children, and that the milk of tuberculous cows is the common source in these cases. Probably at no distant date the contention of Calmette will be accepted that *in the immense majority of cases pulmonary tuberculosis is not contracted by inhalation*, but, as taught by von Behring, the germs enter through the intestinal tract. Future research may explain how in China, where the consumption of the milk of bovines is practically *nil*, tuberculosis is everywhere prevalent amongst the natives.

Berliner Klinische Wochenschrift, July 6, 1908.

Autopsy in a Case of Adams-Stokes Disease.—Karcher and Schaffner say that the interest of the Adams-Stokes symptom-complex lies in its dependence upon a pathological condition of the auriculoventricular bundle of His which causes a dissociation of the heart action. They report the case of a man fifty-eight years old who gave the typical symptoms of the disease, consisting of bradycardia with dissociation of the action of the auricles from the ventricles. During the attacks the radial pulse was thirty-three per minute, while the jugular pulsations were three or four times faster. The frequency of the ventricular contractions was always an aliquot part of the number of auricular contractions; exertion during the attack had no effect upon the frequency of the radial pulse, though the jugular pulsations were markedly increased in number by such influence. The administration of digitalis lowered the number of jugular pulsations quite noticeably, but had no effect whatever upon the radial pulse. The autopsy showed that the heart was hypertrophied and affected by an interstitial myocarditis. Microscopical examination showed that the bundle of His was almost completely changed into connective tissue. Of the twelve cases in literature giving lesions of the bundle of His in Adams-Stokes disease, five showed a condition similar to that observed in the case of the authors'. Other cases showed different lesions localized in the same structure, while in a few cases no lesions of the His bundle could be discovered in the presence of the clinical picture of Adams-Stokes disease. The latter cases, however, are hardly enough to justify a serious doubt that the syndrome is caused by some pathological lesion of the auriculoventricular bundle.

Münchener medizinische Wochenschrift, July 7, 1908.

Significance of Urobilinuria.—Fischler says that the appearance of urobilin and urobilinogen in the urine follows certain well-marked causes and is therefore of interest both to the scientific worker and to the practitioner who is concerned with the diagnosis and the prognosis of disease. Urobilinuria appears in many conditions; this fact, however, does not diminish its diagnostic value. The source of the urobilin is the bilirubin of the bile which is reduced in the intestines by bacterial action and is then again sent to the liver, being reabsorbed from the bowels. Normally the urine contains no urobilin or only very small traces of it. As soon as the common gall duct is obstructed in cases of catarrhal jaundice bilirubin appears in the urine, though in the beginning of the affection and in the very chronic cases the urobilin still is present, a condition which still awaits explanation. In certain cases of liver disease urobilinuria is almost a constant phenomenon,

as, for example, in alcoholic cirrhosis. The appearance of bilirubin in the cases clinically diagnosed as cirrhosis either shows that some complications are present or that the diagnosis is wrong. Urobilinuria in the affections of the liver due to heart disease is frequently present and is in these cases of serious prognostic import. Pernicious anemia is almost uniformly accompanied by urobilinuria, and the pathological appearance of the liver in this disease well explains this finding. Infections and toxemias, finally, are often accompanied by urobilinuria, the liver being very early affected in these conditions. Urobilinuria, therefore, is due to the disturbances of the usual currents of the excretions and secretions of the liver, caused by disease of that organ. Its appearance is of the greatest significance where the condition of the liver is the important factor in the prognosis and diagnosis of disease.

Plastic Operations Upon Nerves.—Spitzy says that in cases of paralysis due to the degeneration of nerves the peripheral portion of the nerve affected may be sutured into a slit of a neighboring healthy nerve, which constitutes the peripheral method of implantation; or the central stump of the healthy nerve may be sutured to the affected nerve, the latter being thus left *in situ*, this being the central method of nerve implantation. The former method is more advisable if the nerve which is used to replace the diseased nerve is itself partially affected. The author has performed such operations in eleven cases of paralysis following anterior poliomyelitis, in which the peroneal nerve was affected and the tibial nerve was used to revivify it. Partial or complete success was attained by these means. Paralysis of Quadriceps extensor muscle of the thigh was treated in a similar manner by the use of the obturator nerve but the results have not been encouraging. Paralyses of upper extremity offer a very promising field for the plastic operations. Partial central implantation is the most advisable procedure in the presence of paralysis of central character. Operations for such conditions in four cases were rewarded with good results. The reappearance of function begins very slowly, the first voluntary movements taking place several months after the operation; electrical irritability follows; if sensory functions have been affected, they always return before the motor functions. The general results prove that the method ought to be widely applied, especially in the paralyses met with in orthopedic practice.

Deutsche medizinische Wochenschrift, July 2, 1908.

Differential Diagnosis Between Appendicitis and the Diseases of the Uterine Adnexa.—Rinne says that such differential diagnosis is always difficult and often impossible. Both anatomically and pathologically the appendix and the uterine adnexa are closely related to each other, the appendiculoovarian ligament affording means of communication between the lymph and blood-vessels of the broad ligament and those of the cecum and appendix. Subjective symptoms, therefore, due to the diseases of one organ may easily give rise to symptoms in the other set. The site of the inflammatory tumor, if any is present, is of value in the differential diagnosis in the early part of the disease only; the appendicular abscesses are more lateral, and increase in the downward direction, the pelvic abscesses are placed more deeply in the pelvis and increase upward. In the latter disease, too, the uterus may be sensitive on pressure. The history of former appendicular inflammation on the one hand or the history of gonorrheal or puerperal infection on the other are of great value in the diagnosis. The initial pain of peritonitis due to an appendicitis is usually general in character, or is felt most in the epigastric and the umbilical regions; there is almost always present a reflex spasm of the overlying muscles, and meteorism develops late in the history of the attack. Gonorrheal peritonitis due to the disease of the adnexa begins with a stormy picture, but very soon the symptoms become milder in character. Meteorism is uniformly present, reflex spasm of the muscles usually absent. In chronic inflammations the diagnosis is still more difficult. It is best, therefore, in all cases of doubt to act as if appendicitis is present and to advise operation. Moreover, all right-sided gynecological inflammations ought to be operated upon by the abdominal and not by the vaginal route, for only the former allows the examination of the appendix, which may be involved.

Experimental Syphilis.—Hoffman, Löhe, and Mulzer have injected large doses of syphilitic virus into the testicles of apes and of rabbits. As a result not only the testicle so treated became inflamed and swollen, but in addition a cutaneous infiltration made its appearance at the site of the inoculation; this lesion appeared thirty-three or thirty-four days after the inoculation, and showed a central erosion and a peripheral limiting wall, being characteristic of the primary sore of animals. The expressed secretion of the lesion contained many spirochetes of syphilis. The regional glands of the ape were markedly swollen. This is the first instance of a cutaneous lesion of syphilis in the rabbit, while the effect in the ape is likewise much more typical than with the usual technique. Experiments are in progress to find out whether the injection of the virus into the testicles is the necessary factor in the production of the cutaneous lesions.

Serum Therapy in Diseases of the Eye.—A. v. Hippel has used the serum prepared by Deutschmann in forty cases of eye disease. He obtained very good results in plastic iritis and especially in cases of serpiginous ulcer, in which the use of the serum obviated the application of the galvanocautery, if the dosage and the frequency of the injections of the serum were carefully proportioned to the severity of the disease. The serum is further of use in plain serous iritis when not caused by tuberculosis; on the other hand it is of no use in infections of the vitreous body. Over two hundred injections of the serum have shown the harmlessness of the procedure and the absence of any local or general reaction. The dosage ranged between 2 and 4 c.c. used daily or less frequently. The explanation of the favorable action of this serum is still to be had, as it is prepared from the blood of animals fed on various yeasts and not by the usual immunizing injections of toxins.

French and Italian Journals.

Non-Existence of Gravidic Pyelonephritis.—Bazy considers it illogical to speak of pyelonephritis of pregnancy, since the pregnancy is not the cause of the pyelonephritis. He believes that the pyelonephritis has generally existed for some time before it is recognized and that the pregnancy is not a causal factor in its existence, but that the occurrence of the two conditions together is a coincidence. It would be better to say pyelonephritis occurring in the course of pregnancy. Pregnant patients suffer from desire for frequent micturition and pain, and no examination is made of the urine, the cause being set down as pregnancy. Only when there is hematuria and fever is any attention given to the condition. Hence we see pyelonephritis in an advanced stage of evolution. The pathology of pyelonephritis in the pregnant and non-pregnant woman is the same and the mechanism of its production is the same. The author believes that pregnancy favors the cure of pyelonephritis. He recommends early examination of the urine of pregnant women and of the ureters, finding out whether the pollakuria is daily and nightly, and placing the patient in bed on diuretic drinks as a preventive.—*La Bulletin Médical*, May 1, 1908.

Surgical Operations and the Value of Ureteral Catheterization in Calculous Anuria.—M. Pavone describes cases of calculus treated by him. In some of these cases he was able, by the use of the urethral catheter, to dislodge the calculus, even when anuria had lasted from one to four days, and the anuria was relieved as soon as the calculus was removed. In some of these cases he injected through the ureteral catheter a small amount of cocaine-adrenalin solution, which caused the spasm of the ureter to disappear, and this having passed away the calculus was displaced by the urine. In some of these cases cystoscopy showed the urine flowing from both ureters. This proves that the anuria is reflex from the obstructed kidney to the opposite ureter. The author advocates the use of the ureteral catheter in every case of anuria. If there is found to be calculus, or when there is a cicatricial contraction the operative indications are different. The precise seat of the calculus may also be ascertained in this way. Nephrotomy arrests the uremia and causes the removal of the calculus.—*La Riforma Medica*, June 15, 1908.

Treatment of Puerperal Infection with the Lactic Acid Bacillus.—M. A. Brindeau has made use of a bouillon of the lactic acid bacillus cultures mixed with sterilized milk sugar, as a remedy for puerperal fever. The remedy depends on the fact that the streptococcus will not grow in an acid medium and as the lactic acid bacillus is nonpathogenic it is used to produce an acid medium. The bouillon is used for vaginal and uterine packing and injections, no antiseptic injections being given either before or after its use. He gives the history of three cases treated in this way with recovery. The condition of the vagina and uterus improved rapidly and the fever was lessened. No bad results were observed and all three patients recovered. The author advocates further use of this remedy until a thorough test of its efficiency has been made.—*Bulletin de la Société d'Obstetrique de Paris*, April 16, 1908.

Book Reviews.

Clinical Lectures and Addresses on Surgery. By C. B. Lockwood, Surgeon to St. Bartholomew's Hospital. London: Henry Frowde, and Hodder and Stoughton, 1907.

This is one of the most recent volumes of the "Oxford Medical Publications"; and, we may add, one of the very best. The book contains fifteen Lectures and Addresses, on the following topics: Introduction to the study of clinical surgery; clinical reasoning; the course of intra-abdominal inflammation; on the recognition and management of intestinal obstruction; the essentials of a diagnosis; secondary infection of lymphatic glands in malignant disease of the tongue; carcinoma of the breast, and its spread into the lymphatics; varicose veins; swellings in connection with the scrotum (two lectures); exploratory laparotomy, especially in case of malignant disease; fecal leaks and fistulæ; the immediate microscopical diagnosis of tumors during the course of operations; clinical pathology in its relation to diagnosis and treatment; and salivary calculi. The whole makes a small volume, full of good material, well written, and very readable. The book can be recommended to recent graduates, about to take up their hospital work or private practice; it is also well worth the perusal of older practitioners.

The Prevention of Infectious Diseases. Being the Lane Lectures delivered at the Cooper Medical College, San Francisco, in August, 1906, and revised for publication. By John C. McVail, M.D., D.P.H. Camb., F.R.S.E., County Medical Officer for Stirlingshire and Dumbartonshire; Lately Examiner in Medical Jurisprudence and Public Health in the University of Edinburgh, and now in the University of Glasgow; Ex-President of the Incorporated Society of Medical Officers of Health of Great Britain, and of the Incorporated Sanitary Association of Scotland. London: Macmillan and Co., Limited, 1907.

This volume consists of a course of lectures on the prevention and control of infectious diseases. The subject is of the utmost importance, and the author has here put together the results of an unusually wide experience, as a Health Officer, in dealing with these diseases and conditions. The first lecture is on Public Health Organization in Great Britain; and it contains much that is of value on the duties of a medical officer of health, his qualifications, and his relation to and attitude towards the doctors in his district. The succeeding lectures are on the prevention of the following diseases: Typhus fever, enteric fever, plague, measles, scarlet fever, diphtheria, smallpox, and tuberculosis. There are several illustrations, plans, charts, diagrams, and maps which all help to elucidate the text. At the end of most of the chapters there is a leaflet dealing with the prevention of the given disease, drawn up in simple language, and suitable for distribution. These lectures are a valuable contribution to medical study, whether viewed from the standpoint of Practice or of Hygiene; and the present work is a worthy successor to the previous volumes which have been published as The Lane Lectures. It is the least technical of the whole series, and appeals to a wider circle of readers than any of its predecessors.

Nervous and Mental Diseases. For Students and Practitioners. By Charles S. Potts, M.D., Professor of Neurology in the Medico-Chirurgical College of Philadelphia; Neurologist to the Philadelphia Hospital; formerly Associate in Neurology in the University of Pennsylvania. Second edition, revised and enlarged. Illustrated with 133 engravings and 9 plates. Philadelphia and New York: Lea & Febiger, 1908.

We are glad to note that this little manual has been brought up to date in a second edition. Most of the important advances in neurology that have been made since the appearance of the first edition have been incorporated, and the chapter on mental diseases has been rewritten in conformance with the newer classifications. Many new illustrations and a number of plates enhance the value of the work. A scheme for neurological examinations is another important addition. A thorough examination of the patient in all cases of nervous disease is of the utmost importance, and if we might offer a criticism it would be that the scheme introduced is scarcely adequate. Such methods of examination are best studied in more complete and fuller works on both nervous and mental disease, or, perhaps, in some volume devoted solely to this part of the subject. A great deal of information is, however, condensed in the book, the size of which has been augmented to about 550 pages. The further study of many subjects not fully described in the text is facilitated by occasional references in footnotes to selected authoritative articles, especially those of more recent date. Among these references it is interesting to note a preponderance of American and English writers. In such small manuals covering broad fields even more references to original works in foreign tongues are frequently valuable. The busy general practitioner especially will find Dr. Potts' book convenient and generally reliable.

Nierendiagnostik und Nierenchirurgie. Von Dr. G. Kapsamer. Two Volumes. Vienna: Wilhelm Braumüller, 1907.

Dr. Kapsamer is associated with von Frisch at the latter's great surgical clinic for urinary diseases in Vienna, and the material for these two volumes was gathered from the records of the Vienna clinics, as well as from the author's private practice.

The first volume is devoted to renal diagnosis, the second to renal surgery. After a brief introduction the various methods of examining the kidneys are taken up. In the section on urine analysis the author discusses in great detail the various new methods of functional renal diagnosis. Next the methods of separating the urine from each kidney are considered. Among the functional tests he favors the phloridzin method, as it gives the most accurate results. Ureteral catheterization is the best method of separating the urines, while the so-called separators often fail when they are most needed. Ureteral catheterization is neither as difficult nor as dangerous as the supporters of the separators would have us believe.

In the next section the relationship of the secretion of each kidney under various conditions is considered, and the author gives an elaborate record of animal experiments and of cases which prove that the presence of a catheter in the ureter on one side stimulates that kidney to secrete more urine; that there is a reflex effect on the kidney when the ureteral catheter is introduced. This effect is usually a mere increase in the amount of water secreted while the solid constituents remain the same. The closing section of the first volume deals with the various functional tests, *e.g.* the phloridzin test, etc., as applied to the separate urines of each kidney. A bibliography of 1,827 separate titles closes this volume.

The second volume deals with the following topics of renal surgery: Tuberculosis, tumors, cysts, stone, pyelitis, nephritis, and ureteral fistulæ. An appendix deals with the behavior of the second kidney after a nephrectomy and with the question of anesthesia in renal surgery. In this volume there are inserted the histories of a large number of cases—a number too large to allow of a perusal of each case even by special students. Therein lies perhaps the only fault of the book. The tendency to quote cases in a systematic treatise has been done to death by some writers. Case histories are well enough when they illustrate special points, and then they should be brief. An elaborate case history diverts the mind of the student from the original purpose of the book, and a number of these is wearisome to any reader, no matter how patient.

In speaking of certain types of nephritis accompanied by hematuria the author declares that there is no such thing as "essential hematuria." He is right; for this expression has been too long tolerated in modern renal we are very ignorant. There may be slight lesions in the kidneys which appear healthy, but which bleed freely from time to time.

The work of Kapsamer is destined, no doubt, to become one of the standard works on renal diagnosis. It is a monument of patience and of minuteness of detail too great to be grasped at a single reading, and it is probably the most complete discussion of the problems of renal diagnosis that has as yet been presented in modern surgical literature.

A Text-Book of Physiological Chemistry. By Olof Hammarsten, late Professor of Medical and Physiological Chemistry in the University of Upsala. Authorized translation from the author's enlarged and revised sixth German edition. By John A. Mandel, Sc.D., Professor of Chemistry in the New York University and Bellevue Hospital Medical College. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1908.

Biochemistry is a comparatively new science, at least in its modern development, and treatises dealing with it are not many. This is perhaps owing to the fact that one of the earliest works on the subject was this treatise by Hammarsten which is so comprehensive and so accurate that other workers find little incentive to enter the same field. This fifth English from the sixth German edition is almost a new work, all of the chapters having been subjected to a comprehensive revision and some of them having been entirely rewritten. That five editions of such a work have been called for in fifteen years shows not only that biochemistry is a progressive science but also that it is one which is attracting a considerably increasing number of research workers.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENITOURINARY SURGERY.

Stated Meeting, Held January 15, 1908.

DR. MARTIN W. WARE IN THE CHAIR.

Vesical Signs Premonitory of Syphilitic Tabes.—Dr. V. C. PEDERSEN presented a patient with vesical symptoms premonitory of tabes dorsalis. The man was 36 years old, white, Canadian, married, telegrapher. He had had gonorrhea four times, the last attack seventeen years ago. About the same time a single chancre developed beneath the foreskin, for which he received treatment with calomel powder at a drug store for a few weeks. His secondary symptoms appeared in due course, but the time of their appearance was uncertain and seemed to have been rather late. His tertiary lesions seemed to have been developed early; a slight paralysis of the right hand appeared fifteen years ago. Dr. Pedersen was of the opinion that this might have been an occupation neurosis since he was a telegraph operator. The physical examination revealed a well-nourished man, slightly anemic, who showed some staggering with his eyes closed; otherwise there was good muscular coordination. His pupils reacted sluggishly to light and accommodation. The muscles of his eyes were normal in action. In walking with his eyes closed the patient's muscular sense seemed to be good. There were no obvious signs of syphilis so far as the mucous membrane, glands, bones, and joints were concerned. Bladder symptoms began three years ago and were then marked with hesitation, occasional obstruction, followed by frequency, distention, and disability to urinate; the stream frequently dribbled; there was little tone to the bladder. The urine at the present time was clear and normal. For a period of several months (about two years ago) his urine was regularly drawn with the catheter twice a week. He had had several crises of pain in the shins. His occupation of telegrapher had carried him all over the United States, so that he had been in the hands of competent specialists in Detroit, Los Angeles, and Seattle. The treatment which in his experiences had been most beneficial was constitutional treatment of the syphilis with washing the bladder out twice a week and the use of the electric vibrator. When first seen by Dr. Pedersen, on December 30, he was in the midst of an attack of vesical irritation, urinating only three times by day, but three or four times by night with hesitation; the size of the stream varied, and he had one attack of inability to pass his water, lasting five hours. He could not urinate at all in the office, so that eight ounces of normal urine were withdrawn by catheter. Seven days thereafter the man was in much the same condition; the vesical irritation had increased, rectal irritation had appeared, and a moisture at the mouth of the penis. Three days thereafter all these symptoms had improved, his nocturnal urination decreasing to two. Three days later he again had a relapse, so that all his symptoms were materially worse excepting the hesitation. During the week preceding this last visit he had had, however, no attacks of inability to urinate. The treatment that the patient was now under was active antisyphilitic, with internal measures, with massage of the prostate, alternating with deep urethral instillations of weak nitrate of silver.

DR. GEORGE K. SWINBURNE said he had seen a few cases of vesical tabes. He recalled one case in which the first appearance of the tabes was in a progressive and almost complete impotence.

DR. FRANCIS C. EDGERTON said he had seen a few cases of beginning tabes with urinary symptoms, and one case in particular was very interesting. This patient had to get up at night as a rule to pass his water, and passed it every two or three hours during the day. One year later he held his water twelve hours and had no desire to pass it at all.

DR. JAMES PEDERSEN said that these cases of tabes were very interesting because they were not so very uncommon. He asked if the residual urine had been tested, and whether indulgence in sexual intercourse in any way affected his ability to hold his water, or affected his attacks of retention.

DR. VICTOR C. PEDERSEN replied that the residual urine had not yet been tested. So far as he was able to judge, sexual intercourse had no effect.

DR. JAMES PEDERSEN said that he had had a typical case in which the man had a hesitancy to start, a tendency to interrupt the stream of urine, attacks of retention, etc. The minor points remained to be worked out in the patient presented. If the patient had a chronic congestion of the prostate, or a relaxed prostate, he thought massaging the prostate with a cold sound, or giving instillations of silver would aid in the recovery of the patient. He asked Dr. Pedersen what form of antisyphilitic treatment he used.

DR. VICTOR C. PEDERSEN replied that, because of the anemic condition of the patient, mouth medication had been employed, but he expected to give the intramuscular injection treatment soon.

DR. MARTIN W. WARE recalled a publication of Dr. Squire's on some lesions occurring in spinal nerve conditions, with disturbances of the bladder. It was very important to find out whether the enlarged prostate was responsible for the retention and other urinary disturbances or not; when the patient was beyond the age of forty years, it was necessary to decide whether the symptoms were due to prostatic or spinal lesions. The cystoscope was one of the readiest and earliest means of making a diagnosis, especially when one saw those muscular bundles in the bladder. When one found bladder retention, or difficulty in voiding the urine, or emptying the bladder completely in young men about 40, a good thing to do was to take the cystoscope and attempt to find these trabeculæ. This would show whether or not the case was of spinal origin. He reported a case that he had under observation, a young man who sought aid in a city hospital for pains of his right side; he was operated upon for a supposed appendicitis. At that time he had bladder disturbances. The operation was successful, but he still had his bladder disturbances, and came to the Mount Sinai Hospital complaining of pain. His urine was clear. He was thirty-eight years old. At times he had incontinence, and sometimes he could not void a single drop of urine. Nothing pathological was found in his urine. The cystoscopic examination revealed a trabeculated bladder and no prostatic enlargement. Further examination revealed ankle clonus, increased reflexes, etc., and a neurologist confirmed the diagnosis. There were nystagmus, tremor, and a complete picture of multiple sclerosis.

DR. VICTOR C. PEDERSEN said that if the patient had not shown so many signs of tabes he would have performed cystoscopy. He believed one should be a little careful about these systoscopic examinations when one could promise the patient nothing more than a confirmation of an already established diagnosis. For the same reason he doubted the wisdom of passing a sound unless the bladder was subsequently irrigated. The urine now was absolutely clear. The sexual history no doubt accounted in part for the irritability of the bladder; there was no doubt some prostatic congestion. Nevertheless, the presence of the typical early signs of tabes made him believe there was a predominating syphilitic deposit in the spinal cord. The first symptoms might be cardiac, pulmonary, ocular, or referable to the lower extremities, or rectal or bladder, together or alone, or gastric. Subsequently one found the sensory disturbances in the lower extremi-

ties. He believed that the diagnosis in this case was correct beyond reasonable doubt.

A Case of Postoperative Enuresis After Prostatic Abscess.—Dr. V. C. Pedersen presented a patient suffering from dribbling after operation for abscess of the prostate. The patient was an American, white, 30 years old, married, laborer. He had had gonorrhea twice, the first time eleven years ago, the last time five years ago. Abscess of the prostate appeared to have developed long after this attack; for this he underwent operation in January, 1907. His first urine was now clear and at times shreddy. His second urine was clear. His sexual habits had always been active and rather excessive in and out of married life. His trouble dated back one year, to the time of the operation. The lesion appeared to be a lack of control of the neck of the bladder following an operation for drainage for abscess of the prostate. He had been treated by physicians privately and in dispensaries all over the city during the past year, with practically all known methods, sounds, instillations, and irrigations, excepting perhaps electricity. Pain was present, moderate and intermittent. The course of his condition appeared to be stationary. By day his urine dribbled constantly if standing, but less if sitting. By night he was able to hold his urine for a few hours. He was obliged to wear a rubber bag by day. All the methods of treatment adopted had failed. Operation had not been recommended. When examined by the urethroscope the patient seemed to have an open mouth of the bladder, which did not close very well over the end of the tube, a lumen being left, apparently the size of a straw. It was only after the urethroscope had been withdrawn a considerable distance that this lumen disappeared, and the mucous membrane closed normally over the instrument. In the deep urethra urine mounted up into the instrument almost constantly. A mucoid discharge was also present. This cystoscopic examination was negative, except that the floor of the bladder was slightly pocketed and the neck of the bladder by retrospection was reddened. Rectal touch seemed to show an abscess cavity filled with cicatrix in the left part of the gland. On the right side there seemed to be left some prostatic tissue. The case was presented, not in criticism of the operation or its result, but in order to bring out suggestions for treatment.

Dr. Francis C. Edgerton asked Dr. Pedersen if a prostatectomy had been performed. All were familiar with the fact that, following this operation, dribbling of urine frequently followed. In a number of cases where prostatectomy had been performed, many times the patients would have erections, but with no emission. There was no seminal fluid.

Dr. A. A. Berg asked Dr. Pedersen how soon after the operation the enuresis developed.

Dr. Pedersen replied, right away. Since his discharge from the hospital he could not hold his water and he returned to see somebody regarding it. So far as the history went, this incontinence developed immediately. Prostatic tissue was there, but the prostate was extensively destroyed.

Dr. A. A Berg said that, with regard to prostatectomy having been done in this case, he did not see what could have prompted such a procedure, and, therefore, he was inclined to the view that it was not done. It seemed to him that an abscess of the prostate, with considerable sloughing, might influence the muscles of the bladder, as traumatism and infection might influence muscles elsewhere, and so result in incontinence. He recalled the case of a child who fell on a beam and sustained a laceration of the membranous urethra with extravasation of urine in the perineum. An extensive perineal slough or phlegmon developed, and, following this, the boy had incontinence for about three years. Then complete continence of urine was established. He thought that accompanying a phlegmonous inflammation of the prostate there was possible a disturbance of innervation which might result in a temporary incontinence of urine, and from which recovery might occur spontaneously.

Dr. A. V. Moschcowitz asked Dr. Pedersen if, from the nature of the scar in the perineum, he could express an opinion as to what operation was done. This might explain the incontinence of urine. A wide incision and division of the various nerves, perhaps on both sides, going to the extrinsic muscles, might have much to do with the incontinence of urine. He had seen some cases following perineal prostatectomy. It was not clear to him in perineal prostatectomy that the incontinence of urine was ever due to the removal of the prostate. In the cases in which it did occur it was due to interference with the nerve supply.

Dr. William C. Lusk asked if Dr. Pedersen had used the urethroscope in this case. He said that the incontinence was probably due to impairment of the constrictor urethral muscles rather than to nerve interference, since the nerve trunks were in close relation with the rami, and therefore pretty well protected.

Dr Pedersen replied that he had, and had found a bladder zone three-quarters of an inch long of cicatricial deformity. After passing that zone he found the urethra behaved normally and closed down over the urethroscope. This zone was far back in the neck of the bladder and was made up of a cicatricial deformity. The dense cicatrix occupied, it seemed to him, the region of the membranous urethra and region of the prostate. He thought that there was some prostatic tissue present, especially on the right side. He had asked the patient to urinate. He stood up and passed eight, ten, or twelve ounces and in a good, forcible stream. Four times he interrupted the flow absolutely, shutting it off suddenly and completely. He said that when sitting he could hold his water indefinitely, but when walking it dribbled. When Dr. Pedersen asked why he shut off his urine, he replied that he had been so instructed in order to cultivate the neck of the bladder. He ventured to suggest that the man could hold his urine better than he thought he could. He believed that if this man was compelled to work and told to pass his urine every two or three hours, he would be able to work, and work better than now.

Dr. V. C. Pedersen said that, with regard to the postoperative enuresis case, he obtained the diagnosis from the patient himself. The form of the scar was irregular, and therefore he could not answer Dr. Moschcowitz's question. The amount of cicatrix present indicated that there had been an inflammatory process. The patient also told him that the doctor said he had an abscess of the left part of the gland and what seemed to him to be the remnants of the prostate, which were chiefly on the right side.

A Case of Urethral Calculus.—Dr. George K. Swinburne presented this report and specimen. The specimen was of interest because the patient declared that until two weeks before he appeared at the dispensary he had never had any symptoms. He then had a sudden sharp pain while urinating and stoppage of the stream and bleeding. He was twenty-three years old and came to the dispensary the latter part of last winter or early spring. He suffered during the two weeks a great deal of pain and passed his urine only with difficulty. He had consulted several physicians, but apparently the correct diagnosis had not been made until he came to the dispensary. The calculus could be palpated just behind the penoscrotal angle as a lump in the urethral canal. Under cocaine Dr. Swinburne attempted to remove it with the urethral forceps, but they only slipped off when traction was made. He was then admitted to the Williamsburg Hospital and, through the courtesy of Dr. Muren, Dr. Swinburne was invited to operate. When the patient was under ether

he again attempted to remove the calculus with the urethral forceps, but without success. So the urethra was opened in the perineum, and with a pair of artery forceps passed forward in the wound the calculus was grasped and readily removed. From its shape it would seem that it must have lodged in the posterior urethra for a long period of time, and there was a groove along either side of the calculus as if made by the stream of urine. The patient made a quick recovery, and he only saw him at the dispensary once afterward, and then lost sight of him. Dr. Swinburne said he would like to have made an examination of his posterior urethra and bladder, but the patient never returned for it.

Dr. Martin W. Ware reported the case of a patient with a vesical calculus. Stone was removed by suprapubic incision. The patient later experienced great bladder irritability and incontinence, and one day all the symptoms abated. In the urine that he passed was found a stone of the same diameter and as large as the one shown by Dr. Swinburne, as well as a number of small ones. In regard to Dr. Pedersen's question, he thought it was not necessary to have a stricture present in order to have a stone lodge in the urethra, and he knew of one case that bore out this contention. A man complained of difficult urination, dribbling, etc. He had a discharge present, but its venereal origin was dispelled because there were no gonococci. A hard mass was found in the pendulous portion of the urethra. Under cocaine anesthesia the stone was removed. There was no stricture in this case. The peculiar thing about this case, however, was that he afterwards developed a dense stricture. At the time he had no stricture at all. The stone became impacted because there was edema about it. The patient afterwards developed a keloid. A resection was done with an end-to-end anastomosis of the walls. Three years later he examined the canal and found it absolutely normal and a patent urethra which admitted a 30 French sound. Dr. Ware's point was that he did not think that it was necessary that a stricture should exist in order that a stone might lodge in the urethra. It might occur because of the obstruction caused by the edema.

Dr. George K. Swinburne said that this patient had no stricture. The stone had lodged at the normal narrowing of the canal. The urethra was large enough for the stone to come through, but it lodged because the edema prevented its passing through. He passed a 28 urethroscope down upon it in the hopes that perhaps he could bring it through, making a channel for it. That did not succeed. The edema of the tissues held the stone where it had become lodged.

Dr. Martin W. Ware asked if anyone had had experience with injecting the urethral canal to distend it with paraffin oil, then attempting to massage while compressing the meatus, or asking the patient to pass his urine, depending upon the *vis a tergo*.

Dr. George K. Swinburne replied that he had injected into the urethral canal castor oil and tried to massage the stone out. He recently had in his office a patient with a urethral calculus. This had occurred the second time. The first time he was able to remove it by forceps. This second time he could grasp it with the ordinary forceps, and he bit into it and then tried to irrigate the pieces out. He was told to return the next day, but the man never returned.

Case of Subcapsular Uronephrosis.—Dr. A. A. Berg presented a kidney showing an interesting but peculiar feature, and for which he wished the Section to give the proper name. The patient from whom it was removed was a child ten months old, who was admitted to the pediatric service of the hospital last summer with the following history: The child was born healthy and had been perfectly well during the first few months of its life. The photograph of the baby when about three months old showed him to be the picture of health. When about six months old the mother noticed that the child was gradually failing. After a bath one day the mother noticed a lump in the right side of the abdomen. This lump increased in size and the child became very peevish. He continued to lose in weight. There were no urinary disturbances. The child had had no febrile disease and had not been sick prior to this time. It was the loss in weight and the peevish condition of the baby that prompted the mother to bring the child to the hospital. This was between the eighth and ninth months. The physical examination revealed a healthy child, with absolutely normal urine, but occupying the right side of the abdomen and extending into the loin was a large tumor the size of the child's head; a characteristic renal tumor. There was a deep sense of fluctuation. The baby was kept under observation for some weeks. No changes were noted in the blood examination, and there were no changes in the urine. The size of the tumor gradually increased, and the weight of the child gradually diminished. Dr. Berg was asked to see the child for two reasons, first to determine the nature of the tumor, and, second, to suggest some method for relief. Upon aspirating the tumor perfectly clear fluid was obtained, which proved to be normal urine. He took it that they were dealing with a congenital hydronephrosis. The presence of this tumor was the cause of the physical condition of the child. Therefore, he proposed an exploratory operation, exposing the tumor and perhaps removing it. Exposure of the tumor by the usual route through a transverse incision was done and he cut down upon the sac. A trocar evacuated 16 ounces of perfectly clear urine. It appeared to him as if the sac represented the remains of the kidney. Thereupon he proceeded to an immediate removal of the sac. The adhesions were dense, making its exsection difficult. The peritoneum was stripped from the anterior aspect of the tumor, and the latter was removed with practically no loss of blood in twelve minutes. He found that he had to do with a large sac. Upon opening this sac he found inside of it a perfectly good kidney. Section of the kidney revealed a much dilated pelvis. The ureter was kinked in passing through the thickened sac. A fistula led from the pelvis of the kidney through its cortical substance to a cavity beneath its fibrous capsule. He considered, therefore, that he had to do with a congenital hydronephrosis, which for some reason, to which the child's history gave no clue, communicated through the fistula in the cortex with the subcapsular space of the kidney. The urine gradually accumulated beneath the capsule, because the outlet of the pelves through the ureter was compressed. As the accumulation increased it stripped the fibrous capsule from the kidney and thus formed a large urinary sac, the outer wall of which was formed by fibrous capsule of the kidney and the inner wall by its cortical substance. The child died twelve hours after the operation. The post mortem revealed an atrophic kidney of the left side and an abnormal implantation of the ureter in the bladder. It seemed to be a congenital hydronephrosis which penetrated through the cortex; the capsule proper of the kidney was so dilated that it held eighteen ounces of urine. What the cause for the deterioration of the child was he could not state. There were no urinary disturbances at all. The case was certainly a unique one in the literature.

Prevesical Abscess.—Dr. Eugene H. Eising read this paper. He said that in 1856 Retzius presented to the Academy at Stockholm the first detailed description of this space, indicating at the same time the surgical importance of that region. The prevesical space was one peculiarly designed for its special function. Its contents were a mass of loosely reticulated connective tissue enclosing masses of soft fat; there were few blood-vessels and some lymphatic glands. The boundaries of this space were in part fixed and in part flexible, which, together

with its soft contents, permitted of the distensibility of the bladder. The surgical features of this region were dependent upon the arrangement of the fasciæ contributing to its formation. After describing the anatomy of this part in detail he said that the present conception showed a marked deviation from the original one of Retzius, describing three spaces instead of one, the prefascial or retromuscular, the prevesical, and the preperitoneal. These he illustrated by diagram on the blackboard. His description was not only academic, but found its practical application both in an intelligent interpretation of the etiology of infections of this region and in their treatment. The obscure etiology of prevesical infection had led many observers to overlook the initial causes and to consider many of the cases to be idiopathic in origin. It seemed probable, however, that prevesical suppuration was rarely if ever idiopathic. Honsell adopted the classification of Englisch, who divided these infections into idiopathic, traumatic, metastatic, and secondary. Dr. Eising considers, however, that for all purposes a division into two classes, primary and secondary, was all-sufficient. The cases hitherto reported as metastatic have been post-typhoidal. Infection of the prevesical space from traumatic causes included all those cases resulting from infection from external or internal injury, directly or indirectly applied, and found no place in this discussion. Eliminating those of traumatic origin, a study of the reported cases of prevesical abscesses revealed the fact that the great majority of cases bore a distinct relation to foregoing inflammations and must, therefore, be considered as secondary. The most prolific cause of suppuration in the prevesical space was inflammatory conditions of the urethra, prostate, and bladder. Other causes were inflammation of the abdominal wall and subperitoneal tissues, suppurations in the pelvis, etc. In the female infection might emanate from diseased internal genital organs and in children more especially from the intestine. He then reported a case in detail, which was important because it deserved mention among the list of cases to be mentioned and because certain clinical features had been studied which had been neglected in other cases. The infection in this case emanated from an infectious nidus in the prostate, excited by catheterization and carried by the lymphatics to the anterior vesical lymph glands. The cases in the literature divided themselves into the following etiological groups: 1. Infection from the urethra and prostate. 2. Direct infection by perforation of anterior bladder wall. 3. Infection from tuberculous adenitis in the vicinity. 4. Infection from the female genital organs. 5. From osteomyelitis of the pubis. 6. Infection from the intestinal tract, including that from the appendix. The symptoms were divided into two groups, the prodromal and the tumor formation. Honsell said that no prodromal period existed, some cases beginning with tumors and in others death might supervene before that event. One case occurred at the age of sixteen months and another at nine years. The condition was more frequent in the male. In consequence of the fact that the prevesical space was practically always, except in traumatic cases, secondarily invaded, there must precede a group of symptoms referable to the primary lesion. From the time the prevesical space became invaded there was a similarity of symptoms. Pain was the predominant symptom; it was not necessarily severe, but was difficult to locate in the milder cases. There was some tenderness, which became marked only with the appearance of the tumor. The patient stooped forward in standing or walking in order to prevent contraction of the abdominal muscles. The tumor might appear early, but usually appeared late, and was usually in the median line, but might be somewhat to either side. It was rarely globular and appeared above the brim of the pelvis; later its lines became more diffused and at a still later period might no longer be globular, but gave the impression of a board-like hardness to the lower part of the abdominal wall. Fluctuation, if it occurred at all, was late and only after the abscess had perforated into the prefascial space, producing an abscess *en bisac*. There might be no urinary symptoms unless the bladder became secondarily involved. The constitutional symptoms were variable. The bacteriology of prevesical abscess had not been satisfactorily investigated. A remarkable issue of these prevesical inflammatory tumors was their spontaneous resolution. The usual termination, however, was by suppuration, which, if not relieved by incision, ruptured spontaneously. A most unfortunate termination was by perforation into the peritoneal cavity, which had been observed ten times. Rupture into the bladder and rectum had been observed.

Dr. William C. Lusk said that he understood the rectus to be attached to the upper border of the crest of the pubes and to the pubic spine. To the front of the pubic bone was attached the pyramidalis muscle, so that the rectus lay against the transversalis fascia. There was no space there at all. With the finger pushed over the crest of the pubis from within the rectus sheath, instead of encountering an attachment of the transversalis fascia to the bone at this situation this fascia receded upward with the bladder and the finger passed unobstructedly into the prevesical space. The two spaces did not communicate. For drainage or diagnostic purposes, therefore, entrance into the lower portion of the rectus sheath, retraction of the muscle outwards, and blunt pressure over the crest of the pubis, would open into the prevesical space. If it was desired, in addition, to make a dependent drainage opening into the space of one side, there existed an easy anatomical approach by cutting along the lower margin of the gluteus maximus muscle, splitting the levator ani and fascia covering it down to the rectal sheath, then passing the finger in this plane of cleavage out to the spine of the ischium over which bony point direct forward pressure would tear through some fascial attachments and enter the sought-for compartment.

Dr. A. A. Berg said he was sorry to differ with Dr. Lusk, but he had seen a layer of fascia behind the pubis and attached there. He had seen also almost the same picture that Dr. Eising had demonstrated on the blackboard. The prognosis in these cases differed somewhat according as to whether the infection was from the intestines or from broken-down glands. But if it was an ordinary staphylococcus infection it took the course of other abscesses.

Dr. George K. Swinburne said he had met with infections in the space of Retzius, but recalled a case told him by a prominent surgeon, a gonorrheal infection of this space, with a typical abscess exactly as Dr. Eising had described. The tumor mass was above the pubis. He cut down upon it and found it to be an abscess and not a tumor, as he first supposed it to be. The man had not had gonorrhea for at least three years. Of course, if there had been an infection of the deep urethra or prostate, gonorrhea would have been at once thought of. But this was a curious and interesting case.

Dr. V. C. Pedersen asked Dr. Eising if in the five or six cases on record in the literature as having disappeared spontaneously the diagnosis was made by mere palpation, or was aspiration done. He doubted whether a fully formed abscess could resolve spontaneously, as there was so much of a tendency to rupture. Edema and infiltration such as followed infections might lead to the diagnosis of an abscess without pus being present, unless aspiration were practised. With regard to the etiology he said he did not remember Dr. Eising mentioning infections of the urachus. When he was in the New York Hospital he remembered Dr. Weir operating upon an abscess of unknown origin. After the abscess was evacuated he found the man had a par-

tially patent urachus, the abscess being situated high in the preperitoneal space. After the abscess was evacuated the man made an uneventful recovery.

Dr. Martin W. Ware said that he was reminded of a case of like nature to the one reported by the secretary, Dr. Pedersen. The abscess had nothing in common with the pericystitis. The abscess was situated higher up. Dr. Ware recalled the case reported by Dr. Eising; the infection was the result of instrumentation. This young man was admitted to the hospital with no discharge. At first he had pain in his abdomen, and two days later he developed retention. Once or twice the urine became cloudy, and there was frequent and painful micturition. When admitted to the hospital there was no gonorrheal infection whatever. The cystoscopic examination revealed a peculiar ulcer and an intense injection of the vessels. This was promptly relieved by instillation of silver. Other symptoms then set in and with the cystoscope there was shown edema of the anterior bladder wall. Edema bullosum was not pathognomonic of pericystitis. This might appear in any inflammatory condition of the bladder. Gynecologists could draw upon this in diagnosticating peculiar positions of the uterus. With regard to Dr. Lusk's remarks, differing with Waldeyer's, Dr. Ware said he took issue. At times in the lining he had seen these fascial layers as definitely marked as demonstrated on the blackboard. As to draining from a dependent point, that of course would seem to be the correct thing to do, but where there was a tendency of the abscess to point above it ought to be incised there. This case was of glandular origin, which in turn infected the cellular spaces. A cellulitis pure and simple could not always be traced. It was often traceable to the glands. It was the French who drew attention in a recent discussion of prostatic abscess to the fact that prevesical abscesses developed from perforated prostatic abscess.

Dr. William C. Lusk said he did not wish to be misunderstood. Drainage should unquestionably be made where the abscess pointed. The idea he intended to convey was that the route mentioned for dependent drainage was an anatomical approach to the space and could be utilized for making a counter opening if desired.

Dr. Eising closed the discussion. Prevesical abscesses might open spontaneously below in the perineum and some burst into the rectum. With regard to the resolution of the abscess, in answer to Dr. Pedersen's remarks he said he did not know whether the abscess had been aspirated in any of the cases reported in the literature, as no mention was made of that fact. He believed, however, that in those cases followed by spontaneous resolution there was no pus formation, and the tumor represented inflammatory thickening, which in this region occurred to an unusual degree.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held March 12, 1908.

Dr. Godfrey R. Pisek in the Chair.

Demonstration of Dr. Fowler's Suction Bell Pump.—Dr. Edmund P. Fowler presented an ear apparatus combined with suction. The general opinion was that the ordinary ear douche did not properly douche this organ, and the device he presented could be used in adults as well as in children. There was a glass bell which fitted around the ear snugly; in the center of this was a little tube to which was attached a fountain syringe. No matter how the child might struggle the apparatus could be held readily in place. He said he had had seven mastoid cases which apparently would have gone to operation, but were aborted by the use of this apparatus. The success was due in part to the local hyperemia produced. This differed somewhat from the Bier method of local hyperemia, in which the whole head was rendered hyperemic by means of the band about the throat. The apparatus sucked the pus to the surface and the douche washed it away. The manometer connected to the fountain syringe, which was placed one foot above the ear, registered 22 mm. of mercury; if placed two feet above, it then registered between 44 and 45 mm. No dizziness was experienced in using this instrument, such as was complained of when the ordinary hand bulbs were employed. The main feature ascribed to this apparatus was the efficiency of the drainage of the pus cavity in the ear, one of the most difficult things to accomplish in aural surgery to-day.

Amaurotic Family Idiocy.—Dr. Charles Herrman presented a baby, fourteen months of age. The parents were Hebrews, and there was no history of nervous or mental disease in the family. The labor was instrumental, and the child was born cyanotic, remaining so for some time. The mother noticed that the baby could not move its arms and legs and did not notice objects. When seven months old the child had convulsions, and there occurred a specially severe one at the age of thirteen months. The patient was almost blind. The head could not be held up, and there was the characteristic cherry red center in the optic disk. The legs were spastic at times. There was present an umbilical hernia and the testes had not descended. There was an optic atrophy. There were no other children in the family.

Dr. Sara Welt-Kakels presented a baby eighteen months old. The parents were not related. There had been five children and it was interesting to note that two had died of the same disease. There was no tuberculosis or lues in the family. The reflexes were increased, sight was diminished, and there were the characteristic changes in the macula and optic atrophy. The speaker did not believe that the changes in the macula were generally understood. In regard to the pathology of the disease it had been shown that there was a degeneration of the ganglionic cells, and the layer of ganglionic cells in the retina was comparatively thick, containing from eight to ten. In the fovea the strata were thin, hence the red color shone through.

The Eye in Amaurotic Family Idiocy.—Dr. Cohen presented an eye that had been removed from a patient with amaurotic family idiocy two hours after death, and which he had preserved in Müller's fluid. There was shown the marked atrophy of the optic nerve, and dilatation of the veins and contraction of the arteries. The bright cherry red spot was well shown in the macula.

Dr. Henry Heiman discussed these cases.

Case of Dextrocardia.—Dr. Sidney V. Haas presented a baby, seven weeks old, who was brought to the clinic because of a gastroenteritis. In making the routine examination the heart was found to be on the right side, but none of the other organs appeared to be transposed. When the baby cried, he became blue. There was a marked systolic murmur heard over the cardiac area.

Dr. Godfrey R. Pisek reported a similar case which had existed for eight years before becoming known. He thought it very strange that such a condition could exist so long before discovery.

Dr. Ward Bryant Hoag reported the case of a man, twenty-five or thirty years old, who never realized that anything was wrong with his heart. A pain, supposed to have been pleurodynia, necessitated an examination of the chest, when the heart was found to be on the right side.

Dr. Herman Schwarz believed dextrocardia to be a rare condition without a transposition of other viscera. The transposition of the heart, viscera, and vessels seemed to go together.

A Case of Lymphangiectasis.—Dr. Henry Heiman presented a baby, eight months old, who had a normal birth. When three months old, a retropharyngeal abscess

was incised and the wound healed in two weeks. The present illness dated back two weeks when a swelling appeared over the left clavicle, which remained stationary. The child was very restless and peevish, but there was no fever. He believed this to be a case of lymphangiectasis, due to some obstruction to the lymphatic circulation. It was to be differentiated from cold abscess, gumma, diffuse lipoma, hernia of the lung, hematoma, and from an aneurysm. By exclusion of these he determined that it was a case of lymphangiectasis. The fluid aspirated was a glairy coagulated fluid.

A Case of Hydrocephalus.—Dr. Montgomery Hunt Sicard presented a baby born of Hebrew parents. When six weeks old the head appeared to enlarge and convulsions were quite common. The bisauricular diameter now was fifteen inches, and the head had a circumference of twenty and three-quarter inches. The enlargement was chiefly upwards. The cranial bones were very much separated. There was a nystagmus as well as a strabismus.

Treatment of Clubfoot.—Dr. Reginald H. Sayre believed that congenital clubfoot could be treated successfully without resorting to tenotomy, if taken early enough; in early life the bones and other tissues were pliable and amenable to dressings applied after pushing the extremity into its normal position. Dr. Sayre presented a patient to demonstrate the application of such an apparatus.

Volkmann's Ischemic Paralysis.—Dr. Reginald H Sayre said that in 1875 Volkmann first drew attention to this condition. After too tight bandaging, as after fractures, such a paralysis might occur. If a constriction was kept on a limb for five or seven hours, the muscles became like boards, bullæ might develop, and paresthesia. If the constriction was not removed at the end of this time regeneration of the muscle cells would not occur. The majority of the cases reported were of the upper extremity. It was necessary to distinguish these cases of ischemic paralysis from hemiplegia and from ulnar nerve paralysis resulting from injury or disease. Dr. Sayre presented a child with a fractured forearm. This member was kept in a splint for seven weeks and with this resulting paralysis. Such deformities came on in a few weeks; whereas paralysis from cerebral causes or from injury of the ulnar nerve appeared after a much longer time. The deformity consisted chiefly in contraction of the flexors of the hand; the flexors of the fingers were not concerned. In the way of treatment Jones of Liverpool had suggested bending the hand well back forcibly, placing it then in a position of hyperextension and applying a properly prepared splint. This had been the method employed in the treatment of the girl he presented. He had treated her in this manner for six months, and it would probably require six months more before she could get her hand under normal control. The blueness of the fingers had nearly disappeared, and sensation was much improved. The bog over the annular ligament had improved a great deal. It should be borne in mind that they were dealing with an altered condition of the muscles; they atrophied and became fibrous cords; the muscles became more or less disintegrated. One stretching would not suffice; one had to work little by little, and day after day, in order to revitalize the parts and cause a restoration of muscle belly. It was not a case of muscle nerve paralysis, but of muscle destruction.

Dr. Herman Schwarz did not believe that pressure alone caused this form of paralysis. Many of these cases reported were not instances of Volkmann's ischemic paralysis but pressure necrosis. He recalled a case of ischemic paralysis in which good results followed shortening the bones. He believed Jones's operation a better method of treatment.

Dr. Sayre said that Powers, Bernays, and another man, whose name he could not recall, had written much on this subject in America, while Lorenz, Lesser, and Volkmann had written extensive articles abroad, and all agreed that it was a most intractable condition to cure or even improve. In most of the cases reported tendon elongation or bone shortening was the method employed. These cases resulted from improperly applied dressings as a rule.

A Case of Anterior Poliomyelitis.—Dr. Dennett presented a child who had a typical attack of this disease last August, with paralysis of all four extremities and of the neck muscles. The paralysis of the four extremities improved markedly, but there was practically no improvement in the abdominal muscles above the umbilicus. All that the patient now presented was this paralysis of the upper abdominal muscles.

A Case of Scrofuloderma.—Dr. Charles Herrman presented a child with peculiar congenital deformities of the hands and feet, asymmetrical palate, deformity of the nose, this peculiar condition of the skin, etc. There was some doubt as to the diagnosis of scrofuloderma, although Dr. Fox had made it. The deeper tissues of the skin were involved, and scars were left. The color of the lesions was a rather characteristic livid red. The lesions were not painful. They were circumscribed. Dr. Schwarz believed the tuberculin test should be made. There was no specific or tuberculous history. This skin condition existed at birth. Scrofuloderma existed for years and did not react to treatment.

A Case of Splenomegaly.—Dr. Dennett presented a case of primary enlargement of the spleen. The child was twelve years old and two or three years ago this enlargement of the abdomen was first noticed. There were no other enlargements. There was no anemia; the child's color was good, and he was bright mentally. There was no luetic or tuberculous history. One brother had an enlargement of the abdomen which was noticed only when he was six or eight years old, and which the attending doctor said was due to an enlarged spleen and liver. He was perfectly well until seventeen years old, when he died of typhoid fever. There were three other children in the family and all were in good health.

A New Jacket for the Correction of Deformity in Pott's Disease.—Dr. Charlton Wallace presented this jacket which had an open space in front so as not to interfere with respiration. The jacket was so constructed that it grasped the pelvis and shoulders and, with the chin piece on, the head. These were the fixed points. Pads were applied over the deformity and pressed on the back in the line of least resistance, *i. e.* anteriorly. The respiratory movements were aids in correcting the deformity. There was no embarrassment to respiration and the organs were not at all crowded. The correction was made by continuous pressure and not by extension. The patients were made more comfortable than with other apparatus. He presented two children wearing this new jacket.

Probable Transposition of the Vessels of the Heart.—Dr. Herman Schwarz presented a boy, nine years old, who had been cyanotic from birth, and who came to the clinic because of a cough. The fingers were clubbed. It was interesting to note that although examined by physicians at divers times this congenital condition of the heart was never discovered. Dr. Schwarz searched for the cause of the cyanosis. After excluding conditions outside the heart which might cause the cyanosis, the cause was then searched for in the heart itself. He outlined the heart. There were no murmurs, but there was a marked accentuation of the second sound. He asked what the conditions were which would give an obstruction and a clear heart tone. A probable diagnosis of transposition of the vessels at the base of the heart was made. The aorta, instead of arising from the left ventricle, arose from the right; and the pulmonary artery, instead of coming from the right ventricle, came from the left. There was a smaller circulation of arterial blood, and a peripheral circulation of venous blood.

A Case of Cretinism.—Dr. Louis Fischer presented a patient, twenty-three years old, a twin brother of a cretin. The twins had been under treatment with thyroid extract for some time and with marked benefit, both mental and physical.

A Case of Cretinism.—Dr. Eli Long presented a little girl, nine years old, who had been treated by him for six years. She practically had no mental development although her physical condition was excellent. He presented photographs of two other cretins.

An Unusual Case of Mastoiditis.—Dr. John J. McCoy reported the case of a girl, nine years old. Two nights before coming under observation she could not sleep because of pain when lying on the left ear. One month before this she had an earache. There had been no discharge from the ear. A large fluctuating mass behind the left ear was incised and a large amount of pus evacuated. The cortex of the mastoid was perforated and through a large opening pus was seen to be coming. The mastoid cavity was found to be filled with granulation tissue and pus. Practically the entire mastoid was involved. The inner plate of the lateral sinus was destroyed. This case was particularly interesting in showing the length of time the process could exist without giving symptoms. It was only when the pus found its way externally that the child complained of any pain. This case was a good illustration of the benefit to be derived from early paracentesis of the drum membrane; had the condition been discovered in time, and a paracentesis performed, such a destructive process would have been prevented.

Early Diagnosis of Pott's Disease.—Dr. Charlton Wallace said that Pott's disease was formerly considered to be congenital, but they now knew it to be tuberculous; tuberculosis of the bones was the same as tuberculosis of the lungs. Deformity might develop without pain or any subjective symptoms. The carriage of the child was peculiar, walking on the toes to prevent jars. These children would not play with others. They lost in weight, and were more or less weak. A diagnosis was not made in many cases because the general practitioner or orthopedic surgeon did not strip the child when making an examination. If one observed the child closely he would see that the patient protected himself in removing the clothes. Sayre's sign would be noted, an especially prominent sign when the disease was located low down. The child would stoop with the back straight. When the patient was on the table the four normal curves of the back would be obliterated if the child was not over six or seven years old. A very important sign was the limitation of motion in all directions. The majority of these cases resulted from lack of prophylaxis in tuberculous families. The orthopedic treatment aimed to prevent and to correct deformity. The prevention of deformity was accomplished by strapping the patient to a frame, and keeping him there. The new jacket was of great value in correcting deformity, and this jacket he believed to be one of the best things in orthopedic surgery to-day.

Philadelphia County Medical Society.

At a stated meeting, held April 22, Dr. Harry A. Duncan made "A Demonstration of the Method of Taking the Opsonic Index." He pointed out that what is required for this purpose is a small amount of blood-serum from the individual under observation, an equal amount of blood-serum from a presumably normal person, a number of washed leucocytes, and an emulsion of a culture of the bacteria underlying the morbid process being studied. By determining the number of bacteria taken up by the leucocytes or the number of leucocytes taking up bacteria in the two specimens of blood-serum a conclusion can be reached as to the opsonic index. This is then taken as a guide to the character and the strength of the bacterial virus to be employed in treatment, as well as the intervals between administration. Dr. Nathaniel Bowditch Potter of New York expressed regret that his experience and that of his colleagues failed to demonstrate any large measure of usefulness for the opsonic index. Their results had been so variable as to make them feel that the procedure is not to be depended upon. Nevertheless, it had been found that opsonic therapy was in the highest degree useful, and an illustrative case was cited in which it was believed that life was saved by the proper administration of a bacterial vaccine. Dr. Nathaniel Gildersleeve expressed belief in the utility of the opsonic index, if not for diagnostic purposes at least for determining the dosage and the intervals of treatment. Dr. G. Morton Illman warmly advocated the determination of the opsonic index and also the therapeutic employment of bacterial vaccines, sustaining his argument by the recital of illustrative instances. Dr. L. Napoleon Boston presented a communication entitled "The Microscopic Diagnosis of Diseases by Blood-smears." He pointed out that the results of examination of the blood were applicable in the diagnosis of various morbid conditions only to the same degree as other clinical manifestations, and a conclusion was, as a rule, no more to be based upon such results than upon any other single symptom. A small number of diseases could be recognized directly from examination of the blood, for example, malarial fever and filariasis. Often leukemia also could be diagnosed by such examination alone; but the accurate recognition of the various forms of anemia required in addition a careful study of other symptoms and physical signs. Even more than the number of erythrocytes and the percentage of hemoglobin diagnostic significance was to be attached to the morphology and the tinctorial reactions of the red cells. Basophilic degeneration of the erythrocytes might be looked upon as distinctive of lead-poisoning. A differential study of the leucocytes was even more important than an enumeration of their number. Eosinophilia with or without leucocytosis should suggest the existence of animal parasitism. Dr. George W. Norris made "A Demonstration of the Method of using the Cardiosphygmograph." He exhibited the instrument of Jaquet and demonstrated its method of application for the purpose of getting synchronous tracings of the cardiac pulsation, jugular or other venous pulsation, and radial or other arterial pulsation. Dr. Wm. Pepper discussed "The Clinical Application of the Cardiosphygmograph," illustrating by means of diagrams the significance of the carotid, auricular, and ventricular pulse-waves and the relation of one to the other. Dr. Wm. B. Stanton made "A Demonstration of the Method of Determining the Blood-pressure." He exhibited the sphygmomanometer devised by him and consisting of a reservoir of mercury communicating with a manometric tube of glass and provided with two arms, one connected with a rubber bag to surround the arm or other member, and the other with a rubber bulb for introducing air into the bag for the purpose of obliterating the pulse distal to the encircling bag. The height to which the mercury rose in the tube with the disappearance or reappearance of the pulse indicated the systolic pressure, while the diastolic pressure was that at which the mercury in the tube made the widest oscillations. The results obtained by this means were not diagnostic of any one or a number of diseases, but they were to be looked upon precisely as any other symptom and were to be considered in their relation to the other clinical phenomena present.

Epithelioma and Syphilis of the Tongue.—My experience has shown me the enormous number of cases where epithelioma has developed in syphilitic disease of the tongue. Hence, I go so far as to say that all chronic tongue cases should be kept under observation at regular intervals.—*Charles Ryall.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

West Virginia State Board of Health.

Parkersburg, April 14, 1908.

ANATOMY AND EMBRYOLOGY.

1. What is the skin? Name and describe its layers, what are its appendages, and where found?
2. Describe the mastoid portion of the temporal bone, and name the muscles attached thereto.
3. Describe the iris, giving its blood and nerve supply.
4. Locate the liver, give its average weight, blood supply, and describe its ligaments.
5. Name the regions of the abdomen. What parts are included in each region?
6. Give the rise, course, and general distribution of the femoral artery.
7. What changes take place in the vascular system at birth?
8. Describe in detail the long saphenous vein, and give the surface markings.
9. Define the term osteoblast, myoblast, sequestrum. Explain sequestrum formation.
10. Describe the musculospiral nerve.

PHYSIOLOGY AND HISTOLOGY.

1. Describe yellow elastic tissue.
2. Describe nerve vesicle, nerve fiber, neuron.
3. What is reflex action? Give example.
4. What changes in brain during sleep?
5. What is the blood composition; blood pressure, to what due?
6. Give process of respiration, to what due, when mostly pectoral, when mostly abdominal?
7. Give normal amount of urine in twenty-four hours, its composition, how much urea?
8. Describe the skin, give its office.
9. Explain the difference between tonic and clonic spasm.
10. Locate the speech center, what may cause aphasia?

MATERIA MEDICA AND THERAPEUTICS.

1. Belladonna: preparations, action, therapeutics.
2. Salicylate: origin, action, uses.
3. Define a diuretic, give an example and explain its physiological action.
4. Name eight anthelmintics.
5. Nux vomica: preparations, therapeutic action.
6. Physiological action of cocaine; treat poisoning. What is cumulative action of a drug? Give example.
7. What is Fowler's solution, Dover's powder, Basham's mixture?
8. Name three direct cholagogues, three indirect cholagogues.
9. Therapeutic value of alcohol.
10. Classify arsenic, chloral, phosphorus, iodine, turpentine, quinine.

CHEMISTRY AND MEDICAL JURISPRUDENCE.

1. Define base, acid, atom, and element.
2. Define analysis, synthesis, reaction, and sublimation.
3. What is normal reaction of urine and what caused by, and how modify abnormal reaction?
4. Give chemical difference between inspired and expired air and what effect on blood?
5. Give characteristics of diabetic urine, cystitic urine.
6. What are incompatibilities? Show by formulæ.
7. What is cause of pain in bite of insect? What local antidote and why?
8. Give steps and findings in a post-mortem investigation of death from asphyxiation.
9. What is the danger of eating peach kernel? Is there any antidote?
10. Give formula for lime water and show reaction when taken into stomach.

BACTERIOLOGY AND HYGIENE.

1. What is cretinism, and with what is it associated?
2. Describe the formation of adipose tissue.
3. Mention the malignant neoplasms.
4. Describe the microscopic appearance of acute parenchymatous nephritis and explain the origin of blood in the hemorrhagic form.
5. Is cerebrospinal fever more generally sporadic or endemic?
6. What habits of school children tend to produce myopia?
7. Indicate a proper diet in the case of diabetes mellitus, obesity, and early convalescence in typhoid fever.
8. Name eight principal carbohydrates used in food.
9. Name three tests of detecting impurities in water.
10. What is meant by natural and acquired immunity from disease? Give an example of each.

PRACTICE OF MEDICINE AND PEDIATRICS.

1. Give cause, symptoms, and treatment of chronic gastric catarrh.
2. Give seat of lesion and symptoms of locomotor ataxia.
3. Diagnose and treat acute articular rheumatism. What are the most dangerous complications?
4. Give cause and treatment of constipation.
5. Diagnose the skin and mucous membrane manifestations of syphilis.
6. Give symptoms and treatment of the following poisons: lead, strychnine, aconite, and carbolic acid.
7. Diagnose and treat ulcerative stomatitis.
8. What instructions would you give the nurse in regard to the care and feeding of a child during the first month?
9. Differentiate epilepsy from other convulsive diseases of children.
10. Give cause, symptoms and treatment of acute meningitis.

OBSTETRICS AND GYNECOLOGY.

1. How is the pelvis formed?
2. Describe the Fallopian tubes.
3. Give theory of menstruation.
4. What is the appearance, weight, etc., of a fetus of the fifth month?
5. How many stages of labor? Describe each.
6. What articles should be taken by the accoucheur to to the bedside?
7. What is the most frequent cause of pyosalpinx? Treatment.
8. Treat eclampsia.
9. What preventive measures, if any, would you take to prevent ophthalmia neonatorum?
10. Diagnose and treat a transverse position.

SURGERY.

1. Differentiate varicocele, hydrocele, cystocele, rectocele, and hematocele. Give treatment for each.
2. Give indications, steps and technique of operation for phimosis.
3. Give surgical treatment for varicose veins of leg.
4. Give operation of tracheotomy, naming indications.
5. Define carbuncle and give treatment, local and systemic.
6. Give symptoms of intussusception, treatment, and prognosis.
7. Give etiology, symptomatology, and treat the different forms of erysipelas.
8. Define, give cause and treatment of Colles' fracture.
9. Describe operation for infusing a patient with normal salt solution.
10. Differentiate fistula and fissure of anus, and give treatment of each.

SPECIAL PRACTICE.

1. What should be included in the history of case?
2. Differentiate between appendicitis and biliary colic.
3. Describe some of the conditions which cause children to sleep with mouth open.
4. Aphonia: is it a disease or symptom of diseased condition? Give causes.
5. Iritis: describe and treat.
6. Describe albuminuric retinitis, its significance.
7. Eyestrain: what are some of the symptoms?
8. Name some of the causes of impaired hearing, and how tested.
9. Describe the so-called "S. Weir Mitchell rest cure."
10. Acute mania: give symptoms.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

West Virginia State Board of Health.

Parkersburg, April 14, 1908.

PHYSIOLOGY AND HISTOLOGY.

3. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve.

Example: The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

4. During sleep the brain receives less blood and fewer stimuli; the cortical centers are dulled.

5. The blood is composed of:

1. Plasma.
2. Corpuscles. { Colored. Colorless. Blood-plates.

The *plasma* consists of water and solids (proteids, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteids, fat, and inorganic salts). The *white corpuscles* consist of water and solids (proteid, leuconuclein, lecithin, histon, etc.).

7. The normal amount of urine passed by an adult in twenty-four hours is about fifty ounces.

The normal constituents of the urine are: Water, urea, uric acid, urates, hippuric acid, kreatinin, xanthin, hypoxanthin; sulphates, chlorides, and phosphates of sodium and potassium; phosphates of magnesium and calcium; nitrogen, and carbon dioxide.

The amount of urea voided in twenty-four hours is about five hundred grains.

8. The *functions of the skin* are: Protection, excretion, secretion, regulation of the body temperature, absorption, sensation, special sense of touch, respiration.

9. In *tonic spasms* the muscle remains for some time in a state of rigid contraction. In *clonic spasms* the muscle alternately contracts and relaxes.

10. The speech center is located in the third frontal convolution, on the left side.

Aphasia may be caused by: Cerebral hemorrhage, thrombosis or embolism; by tumor, or abscess in the neighborhood of the center.

MATERIA MEDICA AND THERAPEUTICS.

3. *A diuretic* is an agent which promotes the secretion of urine. Caffeine is a diuretic; it acts by dilating the renal blood-vessels, chiefly in the glomeruli, it stimulates the secretory epithelium of the kidneys, and also hinders absorbent action in the uriniferous tubules.

4. *Eight anthelmintics:* Santonin, pomegranate, pepo, aspidium, pelletierine, spigelia, quassia, turpentine.

5. Nux Vomica. *Preparations:* Extract, fluid extract, and tincture of nux vomica; strychnine, sulphate and nitrate of strychnine.

Physical action: It excites the digestive secretions, increases the appetite, increases peristalsis, and improves the digestion; it is a vasoconstrictor, it raises blood pressure, and is a cardiac stimulant; it is also a respiratory stimulant; hearing and sight are rendered more acute.

6. Cocaine. *Physiological action:* Local anesthetic, when applied externally; internally, it is a muscular, cerebral, circulatory, and respiratory stimulant, and a mydriatic.

Treatment of cocaine poisoning: Wash out the stomach; give nitroglycerin, amyl nitrite, strychnine, or ammonia; artificial respiration may be necessary.

When a drug is administered for a sufficient time more rapidly than it can be eliminated, a time will come when it will have *accumulated* to such a degree that marked, and possibly toxic, effects will be produced by ordinary medicinal doses.

7. Fowler's solution is Liquor potassii arsenitis.

Dover's powder is Pulvis opii et ipecacuanhæ.

Basham's mixture is Liquor ferri et ammonii acetatis

8. Three *direct cholagogues:* Euonymus, podophyllin, sodium phosphate.

Three *indirect cholagogues:* Mercury, potassium bitartrate, jalap.

9. "Though decidedly injurious in health, in disease alcohol is a most valuable remedy in appropriate cases. In *vomiting* of yellow fever, seasickness, etc., iced champagne is useful. *Atonic indigestion* of nervous and depressed subjects, cautiously. *Phthisis*, it does good if it promotes digestion and assimilation; otherwise it is very injurious. *Cholera infantum, diarrhea*, etc., Cognac brandy in full doses. *Cardiac failure*, brandy in small doses repeated as fast as oxidized. *Chloroform anesthesia*, ℥ j-ij of whiskey beforehand, to sustain the heart, and prolong the chloroform narcosis. *Poisoning* by cardiac depressants and snake venom, alcohol freely, to sustain the heart. In *snake poisoning* it is given *ad libitum*. *Diphtheria*, whiskey or brandy in small doses frequently from the commencement, and dilute alcohol sprayed into the throat, is very efficient treatment. *Adynamic fevers*, small doses frequently are often of great value. *Gonorrhea*, Niemeyer is said to have done a lucrative business by treating this affection with injections of tannic acid in port wine. *Insomnia* from cerebral anemia may be prevented by small doses of some alcoholic stimulant at bedtime. *Wounds*, no better dressing than strong alcohol, to prevent putrefaction and protect the surface by coating it with a coagulum of its own albumin. *Bed sores* if threatening, alcohol locally, to harden the tissue. *Cold* from exposure, may be prevented by a moderate dose of alcohol, to restore the balance of the circulation and prevent internal congestion, by relaxing the vessels of the periphery."—(Potter's *Materia Medica.*)

Example: Digitalis, strychnine.

CHEMISTRY AND MEDICAL JURISPRUDENCE.

1. *A base* is a ternary compound capable of entering into double decomposition with an acid to produce a salt and water.

An acid is a compound of an electro-negative element or radical with hydrogen, part or all of which hydrogen it can part with in exchange for an electro-positive element or radical, without the formation of a base.

An atom is the smallest quantity of an element that can enter into chemical action, or that can enter into the composition of a molecule.

An element is a substance which cannot, by any known means, be split up into any two or more other kinds of substance.

2. *Analysis* is the splitting up of a compound into simpler compounds or elements.

Synthesis is the formation of compounds from elements or from simpler compounds.

Reaction is (1) the action of substances upon certain organic pigments; (2) the mutual chemical action of two or more substances on each other.

Sublimation is the process of converting a solid into a vapor, by heat.

3. The normal reaction of urine is acid; this is due chiefly to the acid sodium phosphate (monosodic phosphate) and acid potassium phosphate (monopotassic phosphate). When the urine is alkaline, benzoic acid may be administered to render it acid.

4. The changes produced in the *air* by respiration are:

	Inspired Air.	Expired Air.
Oxygen	21 per cent.	16.6 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide	0.04 per cent.	4.4 per cent.
Other gases	Rare.	Often present.
Watery vapor	Variable.	Saturated.
Temperature	Variable.	That of body.
Volume	Varies.	Diminished.
Bacteria	Always present.	None.
Dust	Always present.	None.

In the *blood* the changes take place in the capillaries of the lungs, and are: (1) The giving up of the CO_2 by the venous blood, (2) the absorption of oxygen during inspiration, (3) the blood is cooled, and (4) it also loses a small amount of watery vapor.

5. *Diabetic urine.* In diabetes mellitus the urine is enormously increased in quantity, the specific gravity is generally high (1030 to 1045), it contains sugar, has a sweetish odor, is pale in color, and has an increased amount of urea.

Cystitic urine contains pus, albumin, epithelium, triple phosphates, sometimes blood. In acute cases the urine is acid; in chronic cases it is alkaline and ammoniacal.

6. *Physical incompatibility* occurs when a prescription contains drugs which do not act chemically on one another, and so cannot be dispensed without some alteration. *Example:* prescribing an oil and water.

Chemical incompatibility occurs when chemical action not intended by the prescriber takes place between two or more of the ingredients of the prescription. *Example:* prescribing potassium chlorate to be rubbed up with tannic acid.

7. The pain in insect bite is supposed to be due to the presence of formic acid. The local antidote is ammonia water, or dilute alkaline liquid, either of which will neutralize the acid.

8. In death from axphyxiation there will be found:—The right side of the heart and the venous system full of blood; congestion of the mucous membrane of the bronchial tubes; the sinuses of the brain are filled with blood; the brain, liver, spleen, and kidneys will be congested; the blood is usually dark colored.

9. The danger of eating peach kernels is the possibility of being poisoned by hydrocyanic acid.

Potassium permanganate and hydrogen dioxide are said to be antidotes.

10. Lime water is a saturated aqueous solution of calcium hydroxide $Ca(HO)_2$. The reaction when taken into the stomach is:

$$Ca(HO)_2 + 2HCl = CaCl_2 + 2H_2O.$$

BACTERIOLOGY AND HYGIENE.

1. *Cretinism* is a condition of idiocy, associated with imperfect development of the body. It is probably due to some interference with the function of the thyroid gland.

3. The *malignant neoplasms* are: Sarcoma, epithelioma, and carcinoma.

5. Cerebrospinal fever is more generally sporadic.

6. The habits of school children which tend to produce myopia, are: Reading of poor print, or in a poor light, improper positions in reading or writing, using the eyes when tired, and excessive study.

8. *Eight Carbohydrates used as food*: Sugar, fruits, milk, cereals, malt, bread, green vegetables, sweets.

10. *Immunity* is the power of resistance of cells and tissues to the action of pathogenic bacteria. Immunity may be either natural or acquired.

Natural Immunity is this power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired Immunity is this resistance acquired: (1) by a previous attack of the disease caused by the bacteria, or (2) by the person being made artificially insusceptible. The conditions which give immunity from the pathogenic action of bacteria are:—(1) a previous attack of the disease; (2) inoculation, with small quantities of bacteria, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

PRACTICE OF MEDICINE AND PEDIATRICS.

2. Locomotor Ataxia. *Seat of Lesion*: Posterior columns of the spinal cord and posterior nerve roots.

Symptoms: Loss of coordination; characteristic and unsteady gait; tendency to stagger when standing up with feet together and eyes closed; sharp and paroxysmal pain, called *crises;* girdle sensation; loss of knee-jerk and other reflexes; Argyll-Robertson pupil.

3. The most dangerous complications of acute articular rheumatism are: Hyperpyrexia, endocarditis, pericarditis, chorea, myocarditis, pneumonia, delirium, coma, convulsions.

4. *Cause of constipation*: Sedentary habits, improper food, fevers, weakened abdominal muscles, pain of fissure or piles, anemia, disease of the digestive tract, jaundice, hysteria, and intestinal obstruction.

Treatment: Removal of the cause, if possible; regularity of attempts at stool; exercise, abdominal massage, laxative articles of food, water drinking, salines and mild laxatives, enema of soap and water. Catharties should be avoided if possible.

6. *The symptoms of poisoning by lead* are: "Metallic taste; dryness of the throat; thirst; severe colicky abdominal pains, referred particularly to the umbilical region, and relieved by pressure; pulse very feeble and slow; great prostration; constipation; urine scanty and red; violent cramps; paralysis of the lower extremities; convulsions, and tetanic spasms."

The *treatment* consists in removing the cause and administering the antidote, "magnesium sulphate, which brings about the formation of the insoluble lead sulphate, while the purgative action of the magnesia is also useful. It should be preceded by an emetic or by the use of the stomach tube."

The *symptoms of poisoning by strychnine* are as follows: "Strychnine produces a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours."

Treatment: "The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible."

"The symptoms of poisoning by aconite usually manifest themselves within a few minutes; sometimes are delayed for an hour. There is numbness and tingling, first of the mouth and fauces, later becoming general. There is a sense of dryness and of constriction in the throat. Persistent vomiting usually occurs, but is absent in some cases. There is diminished sensibility, with numbness, great muscular feebleness, giddiness, loss of speech, irregularity and failure of the heart's action. Death may result from shock if a large dose of the alkaloid be taken, but more usually it is by syncope.

"The *treatment* should be directed to the removal of the unabsorbed poison by the stomach tube, and washing out of the stomach with infusion of tea holding powdered charcoal in suspension. Stimulants should be freely administered."

Symptoms in carbolic acid poisoning: Buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperature are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark.

Treatment: Emetics, white of egg, stimulants. Alcohol is said to be antidotal.—*Witthaus' Essentials of Chemistry.*

9. *Epilepsy* is characterized by the cry, tonic convulsions, sudden loss of consciousness, dilated pupils, the biting of the tongue, and the emptying of the bladder.

In *syncope* there are no twitchings and the insensibility is not complete; the condition is preceded by faintness, which is absent in epilepsy.

In *hysteria* the tongue is not bitten, the pupils are not dilated, and the child does not hurt himself in any way.

OBSTETRICS AND GYNECOLOGY.

4. At the fifth month the fetus weighs about eight to ten ounces, and is about nine or ten inches in length. The head is about one-third of the total length; and the liver, heart, and kidneys are disproportionately large; vernix caseosa is present; lanugo, hair, and nails also appear.

6. The following articles should be taken by the accoucheur to a confinement: Tablets of bichloride of mercury, or some other material for making antiseptic solution; forceps; ether or chloroform, with inhaler or mask; fluid extract of ergot; hypodermic syringe, with tablets of strychnine, morphine, etc.; needles, sutures, and needle holder; nail brush and nail cleaner; umbilical scissors; carbolized vaseline; stethoscope; male catheter (rubber); a one per cent. solution of nitrate of silver.

7. The most frequent cause of pyosalpinx is gonorrhea.

8. Eclampsia.—The line of *treatment* as laid down by Edgar is as follows: For *preventive treatment:* (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels, the kidneys, the liver, the skin, and the lungs; (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ.

The *curative treatment* includes: (1) Controlling the convulsions (by chloroform, veratrum, or chloral); (2) elimination of the poison or poisons which are presumed to cause the convulsions; (3) emptying the uterus under deep anesthesia, by some method that is rapid and that will cause as little injury to the woman as possible.

9. *To prevent ophthalmia neonatorum:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a one or two per cent. solution of nitrate of silver, immediately after birth.

SPECIAL PRACTICE

1. The history of a case should include: The date; name, address, age, occupation, and civil condition of the patient. Inquiry should then be made regarding the parents, brothers, sisters, and children of the patient; their health, or age and cause of death. Then the previous illnesses or accidents from which the patient has suffered, and finally the present illness must be inquired into. With regard to the latter, note date of origin, manner of origin, the order in which the symptoms appeared, and the chief symptoms which trouble the patient now and for which he seeks relief. The patient should also be questioned about his appetite, frequency of bowel movements, sleep, loss of weight, ability to work, etc.

2. In *appendicitis* the pain and tenderness are in the right iliac fossa; there is rigidity of the right rectus muscle; there are fever and gastrointestinal disturbances, but no jaundice or tenderness of liver and gall-bladder.

In *biliary colic* the pain is in the right hypochondriac region; there is no rigidity of the right rectus muscle; there are chills, slight fever, sweats, perhaps syncope, and vomiting; the liver and gall-bladder are tender and swollen, and there may be jaundice.

3. Some of the conditions which cause children to sleep with mouth open: Adenoids, hypertrophy of tonsils, retropharyngeal abscess, any obstruction of the nasal passages.

4. *Aphonia* is a symptom, and not a disease.

It may be caused by: Laryngitis, edema of the glottis, tumor of larynx, excessive or improper use of the voice, retropharyngeal abscess, paralysis of the adductor muscles of the larynx, involvement of the laryngeal nerves, fixation of the vocal cords by cicatricial contractions, ulceration of the vocal cords, foreign bodies in the larynx, and hysteria.

7. Some of the symptoms of *eyestrain* are: Headache, nausea, vomiting, heartburn, anorexia, dyspepsia, constipation, insomnia, nightmare, neurasthenia, chorea.

8. Some of the causes of *impaired hearing* are: (1) Aural polypi, (2) inflammation of the membrane lining the Eustachian tubes, (3) inflammation of the middle ear, (4) inflammation of the internal ear, (5) disease of the auditory nerve, (6) perforation of the membrana tympani, (7) parotitis, (8) diseases of the throat, blocking up the end of the Eustachian tube, (9) certain drugs, as salicylic acid, quinine, etc., (10) impacted cerumen.

The distinction between ordinary deafness and the nervous form is made by testing with watch or tuning fork. "If the ticking of a watch or the vibrations of a tuning fork are heard faintly or not at all when held at varying distances from the ear (aërial conduction), but become distinctly audible when the watch or the handle of the fork is placed in contact with the skull or mastoid process (bone conduction), the deafness is of the ordinary variety and due to aural disease. If, on the other hand, watch and fork are heard indistinctly or not at all, both in contact and at a distance, the deafness is due to some lesion of the nerve or its connections. In the first case the nerve is normal and can appreciate vibrations brought by the bone, while, through some fault in the mechanism, aërial vibrations are not transmitted to the nerve endings. In the second case the nerve is at fault and cannot appreciate vibrations, no matter how well they may be conducted."—Butler's *Diagnostics of Internal Medicine.*

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending July 25, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	400	173
Diphtheria	175	22
Measles	219	7
Scarlet Fever	131	9
Smallpox	—	—
Varicella	9	—
Typhoid Fever	71	15
Whooping Cough	14	7
Cerebrospinal Meningitis	12	7
Malarial Fever	—	—
Totals	1031	240

The Bacteriology of Bed-Stuffing.—A recent bacteriological report on specimens of rags and samples of flock used for stuffing bed mattresses, cushions, and so forth, has reached us and affords singularly unpleasant reading. In untreated rags as purchased the number of bacteria living and capable of developing in suitable nutrient media varied from upwards of 10,000,000,000 per gram to over 9,000,000,000. The number of *Bacillus coli* and allied organisms of excremental origin was at least 10,000,000 per gram, while the *Bacillus enteritidis sporogenes* was found in the same material. The report further shows that by the adoption of an efficient pressure steam sterilizer this flock can be reduced to a state of bacteriological purity.—*The Lancet.*

Health Report.—The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending July 24, 1908:

SMALLPOX—UNITED STATES.

		CASES.	DEATHS.
Alabama, Mobile	June 27–July 4	1	Imported

DARWINISM AND DIABETES.*

BY R. G. ECCLES, M.D.,

BROOKLYN, NEW YORK.

WHEN hypertrophy of the ventricles follows mitral incompetency what medical man would think of claiming that the hypertrophy was the cause of the disease? We all know that, in such a case, the increased muscular power is but an effort, on the part of nature, to compensate for the incompetency and to thereby prolong the life of the patient. With apparent purpose the normal functioning of the organ is increased. Just as the muscular power, normal to the heart, is thus augmented, even so, in diabetes mellitus, the normal amount of sugar found in the blood is likewise augmented. In both instances we have nothing more than an increased physiological activity. In the case of the heart we are quite sure that the increase in the physiological activity is beneficial. In the case of the circulation what evidence has any one ever produced that can, in any manner, point to a different conclusion? With Bunge[1] we can pertinently ask: "Why should we accuse a normal function of being the cause of a pathological process?" To look back at the origin of organs and their functions, by the light of natural selection, is to become aware at once of the inconsistency of claiming that they can in any manner cause pathological conditions. Every organism, so viewed, is but a marvelous complex of coordinated fitnesses. Myriads of ages of struggle against disease, hunger, adverse physical forces, and adverse chemical affinities, have left to every creature born into the world a heritage of protective appliances with which to battle for the prolongation of the life of the possessor. Its entire structure, from alpha to omega, is nothing but one wonderful system of fitnesses. No spot is left within the bewilderingly complex whole for a single maladjustment in its unimpeded and unimpaired activities. It has reached us through a never-ending struggle that has wiped out, one by one, every trend toward maladjustments. There cannot, in the very nature of that struggle, be a single organism in existence having a natural trend to disease. Such apparent maladjustments as we discern are but relative weaknesses toward conditions over which natural selection has had insufficient play. How, in a world where only the fit have ever been able to survive, could it be possible for positive unfitness to be selected for survival? Heredity is, through and through, but one mass of accumulated fitnesses. Life, physically considered, is neither more nor less than acquired adjustments against dangers. There are weaknesses toward newly arising dangers, but even these are only relatively such. However fit we may ever become there must still continue to be different degrees in strength among different organs and organisms. Even vestigial organs, like the appendix, cannot produce disease. All the harm they are capable of doing is lodged in their inability to resist and destroy certain attacking parasites. This relative weakness, due to disuse, is nevertheless, marvelously strong and resisting toward other organisms that constantly beset it in its highly exposed position. No tissue and no organ has ever been convicted of spontaneously starting disease. From the view-point of natural selection there can be no such thing as a truly hereditary disease. We may have intrauterine malformations of the fetus, intrauterine poisonings, with intrauterine infections, and some of us may, from lack of a better word, call these hereditary, but true heredity is a heritage of health and health-protecting appliances only. It has heaped up an accumulated wealth of health from all past generations. It is our inherent, constitutional capital—our power by which we are able to resist disease. It is, in very fact, the eternal enemy of disease. To accuse heredity of being a cause of disease is to deny the doctrine of natural selection and to claim that the unfit survive. Such a claim is manifestly absurd. Our heredity, so far as it goes, is one of perfect health, as perfect as natural selection has yet been able to make it. We still lack fitness where the race has not been sufficiently scourged by a disease to which we are unfit. The failure is not in what we get from heredity but in what heredity has never yet triumphed over. Those who have sprung from a stock that has been thoroughly weeded of its weaklings in respect to measles are more or less immune toward measles. Those whose ancestors have come out victorious in a war with plague are immune toward plague. Those whose forebears have been sorely afflicted with all or most of our present common diseases we say have excellent constitutions. Those who have sprung from families that have, somehow, escaped these inflictions we declare have poor constitutions. The hardy and the long lived, where equal care to live hygienically has been practised, are the select progeny from among the sufferers of the past. Pathologists may succeed, by juggling with the chromesomes of germ and sperm, in producing unfitnesses that will approximate to what we might consider true heredity, but nature will take perfect care in seeing that such unfitnesses are wiped out. It is one thing to produce unfit forms, but quite a different thing to perpetuate them.

A favorite explanation among some physicians of the cause of diabetes mellitus has been that it is due to heredity. Dr. Saundby, excellent as are most of his reasonings, has dropped into this popular conception. He says that "heredity is an influence too well attested in certain instances to be doubted." On what sort of fact or facts did he venture to base so sweeping a conclusion? Let us read what he gives as the, probably, most convincing case then at his

*Second paper. See MEDICAL RECORD, May 9, 1908.

command. He continues: "thus in one example diabetes occurred in eight members of one family extending over three generations."[2] He did not seem to observe that every such case as this can be explained, with equal perfection, as a case of contagion or as one in which a common fault of diet was the directing factor. If during the three generations there had been an overindulgence in proteid food by all of these members of this family, we would have an ample explanation from the viewpoint of this writer. There can be little doubt but that many such cases could be found in which typhoid fever shows the same succession in one family, yet no one has suggested the hereditary character of typhoid fever. Had the professor attempted to show us that in the distribution of three generations his eight cases displayed Mendelian characteristics there might have been some suggestiveness of heredity, but he nowhere attempts giving such evidence. What would he do with a case like that related by Dr. L. C. Wadsworth in which a family of eleven were all glycosurics?[3] He surely would not contend that diabetes is so universally a hereditary fault that these parents were breeding true. Does not such a case prove too much? But why consider this phase of the subject further? Let those who are not evolutionists adhere to the belief that this and other phases of disease are due to heredity. The consistent evolutionist can resort to no such explanation without stultifying himself. But whatever the explanation that any physician sees fit to hold he should see to it that that explanation is able to cover all the facts and not merely, as is so often the case, only one or two of them. There is a very wide range of known facts connected with diabetes and until we have a theory elastic enough to meet them all we can be quite sure that we *are not* on the right track. The theory that diabetes is due to disease of the pancreas is the one that pathologists have adhered to for over a century. When, in 1889, Minkowski and von Mering, as well as de Dominicis, discovered that ablation of that organ was followed by a fatal form of diabetes everybody thought that there could be little doubt of that theory being substantially true. The operation has since been performed on many animals and at many times. The results being always alike, except in the case of ducks and geese, every effort has been bent toward completing the proof of the assumption. Most of the experimenting has been with the object in view of discovering a pancreatic secretion so essential to metabolism that its suppression would result in the production of glycosuria. So essential have pathologists felt the necessity for such a substance to exist that von Noorden was constrained to assert that "we are not able at the present time to advance the theory of pancreatic diabetes without it."[4] Lepine suggested that this hypothetic substance might be a sugar-destroying ferment which the pancreas pours into the blood. Experiment after experiment was tried in order to discover this imaginary substance, but it all ended in finding that there is no difference in the glycolytic power of normal and diabetic blood. Cohnheim, evidently constrained by the ghost of Lepine's dead theory, sought for an enzyme activator instead of an enzyme. After much research he finally proclaimed that he had discovered such an activator in the pancreas, and that by its use the glycolytic ferment present in muscle and liver was caused to act vigorously.[5] The reader can get some idea of the function of this activator if he will think of the part played by hydrochloric acid in the digestion of albumin in the stomach. The sugar is supposed to take a similar place to that of the albumin and the supposed glycolytic enzyme is believed to act about as pepsin does. Concerning this supposed activator von Noorden asserts that "Embden and R. Claus have completely overthrown the whole of Cohnheim's teaching by some extremely careful work."[6] This work was done in Cohnheim's laboratory. The editor of the *Journal of the American Medical Association* declares that Cohnheim's activator is "apparently a discovery that clears up at least one of the most fundamental processes of metabolism which has evaded solution in spite of much work directed to this end."[7] Wells is even more emphatic in his commendation of the activator, for he says that "although numerous objections to Cohnheim's views have been made, yet the main fact that the pancreas produces an activator substance for a glycolytic enzyme contained in other tissues seems to have been safely established."[8] Dr. Lydia M. Dewitt assures us that she has proven that Cohnheim's activator really does exist, and that it comes from the islands of Langerhans. Regarding the part that these islands play in respect to diabetes she informs us that "Opie, Weichselbaum and Stangl, Wright and Joslin, Herzog, Ssobolew, and many others believe themselves justified in accepting the theory that pancreatic diabetes is due to some disturbance of the function of the areas of Langerhans, while Hansemann, Gutmann, Reitmann, Karakaschew, Herxheimer, Dieckhoff, Benda, and others contend that this theory does not explain and cannot be based upon the facts observed."[9] To add to the confusion we are told that Stoklasa and Czerny, Simacek, Feinschmidt, and others have demonstrated that both muscle and liver are independent of the pancreas in the matter of glycolysis since they can destroy their own sugar. For the islands of Langerhans to manufacture and the blood stream to carry a special activator to muscle or liver is like "carrying coals to Newcastle," as neither of them need it.[10] But if, for the sake of argument, we accept the activator as a demonstrated verity, how much nearer can it bring us toward the solution of the problem of diabetes? It is a well-established fact that diabetes can exist with the pancreas, so far as human knowledge can discover, perfectly normal. Bunge assures us that "There is not a single organ that does not frequently appear normal."[11] Wells tells us that "there occur many cases of diabetes in which no anatomical changes whatever can be found in the pancreas."[12] Flexner gives quite a list of cases in which diabetes existed in the presence of a normal pancreas and informs us that Nauny "in 40 autopsies on cases of diabetes, saw only one in which he considered the pancreas to be the cause of the diabetes."[13] Von Noorden assures us that he has seen several cases "in which so illustrious a pathologist as Weigert reported the pancreas to be in every respect normal, notwithstanding the most minute search for evidence of disease."[14] In such cases as these what can have happened to Cohnheim's activator? If it really does exist does it not add another to the perplexing problems of this disease. Why did it not activate? Was its function suspended in order to let the blood stream be flooded with sugar? We can come to no other conclusion if it really exists.

In seeking for the etiology of diabetes there are very many more things to explain than a supposed loss of glycolytic power or the results of the impaired functioning of any single organ of the body. Any satisfactory theory of diabetes must give some sort of an explanation of the following facts:

(1) Why the apparent waste of sugar occurs.

(2) How transient glycosuria is related to diabetes mellitus in causation.

(3) Why pancreatic and transient glycosuria can occur in nearly all vertebrates.

(4) Why diabetic patients are most common among the rich proteid users.

(5) Why injuries are the common precursors of diabetic attacks.

(6) Why extirpation of the duodenum produces as severe a diabetes as ablation of the pancreas.

(7) Why, in cold-blooded animals, there is no glycosuria in ablation of the pancreas if the liver is removed at the same time.

(8) Why the protoplasm of the muscles is damaged in all severe cases of diabetes.

(9) Why glycogen disappears from the liver and muscles.

(10) Why the heart, leucocytes, renal epithelium, cerebrum, etc., accumulate unusual amounts of glycogen.

(11) Why the kidneys have increased their impermeability toward sugar but have not done so toward any other substance.

(12) Why the body converts other kinds of food into sugar when carbohydrates are withheld.

(13) Why, in starvation, the body consumes its own tissues in order to supply sugar to the blood and keep up the glycosuria.

(14) Why approaching coma can be arrested by feeding carbohydrates.

(15) Why serious cases can be mitigated by feeding them with oatmeal or potatoes.

(16) Why diabetes can exist with the pancreas in a perfectly healthy condition.

(17) Why antiseptics produce a transient arrest of the glycosuria.

For many years there has been a constantly growing sentiment within the medical profession to explain nearly every disease on Darwinian grounds. It is quite true that it has occurred to but few of them that a microbic explanation of disease is essentially a Darwinian one. They have not thought of such an explanation of disease being an acknowledgment of the struggle for existence and the survival of the fit. Microbes battle with us for even the food we have consumed and that occupies our alimentary tract. They enter our circulation and contest with our cells the right to the pabulum there. They even attack the protoplasm of the cells and seek to appropriate it to their own use. Prof. Roger tells us that, "the more we study pathology, the greater we find the intervention of microbes in the majority of toxic processes."[15] Pathologists have been baffled at every turn in their attempts at explaining diabetes by hereditary, chemical, mechanical, and other causes. It seems about time for us to follow the path that has brought light in other manifestations of disease. Why not now call upon the bacteriologists to come to our aid? Are we not able to help them to a working hypothesis which they can test, and by so doing bring us toward a true solution? A bacteriologist is needed who is himself fertile in theories. Such a one is sure to win by using his opportunities to test with care the value of the successive inductions which he makes from the data at his command. His theories are never mere guesses, as is popularly supposed to be the case, but carefully reasoned out conclusions, based on facts and made to conform to well established generalizations. A sound theory of diabetes must agree with and explain all the peculiarities of that disease. It must likewise conform to the established principles of evolution. The first attempt at framing such a theory seldom results in getting one that exactly fits the case in every minutia but it rarely goes wide of the road that finally reaches the truth. Its suggestiveness alone gives it value for, even when it is wrong, it exposes its own weakness, under trial, and thus redirects toward the right. No theory would seem to fit the facts of diabetes except a microbic one. Assuming, then, that it may be due to some kind of microbe, let us see if there are any facts that can guide us in the direction that may discover the kind of microbe that it is likely to be. Romanes tells us that "wherever we tap nature it seems to flow with purpose."[16] This is clearly a Darwinian idea. If only fitnesses survive we should find purpose everywhere. The most obtrusive fact of diabetes is excessive glycemia. Has it a purpose? We can discover none in its direct relationship to the patient. If any exists it must, it would seem, be in relation to an invading microbe. Massee tells us that "sugar in some form is the positive chemotactic substance to which the germ-tubes of nearly all fungi, parasitic and saprophytic, respond."[17] He also tells us that "Miyoshi cultivated fungi in gelatin containing a small amount of sugar, which was separated by a membrane from a second layer of gelatin containing a larger proportion of sugar; the hyphæ bored through the membrane into the layer containing the largest amount of sugar. He also showed that the hyphæ of *Penicillium glaucum* and species of *Botrytis* passed through the epidermal cell-walls of living leaves, which had previously been injected with a positively chemotactic substance."[18] Bacteria that are chemotropic toward dextrose would be expected to behave in a somewhat similar manner. If a kind exists in the intestinal tract that consumes this kind of sugar in preference to proteid, while not refraining from consuming the latter when the former is scarce or absent, it would be well to suspect it of having something to do with glycosuria. If conditions ever arise in that tract in which the supply of dextrose disappears or becomes very scarce the fact that such bacteria can reach the normal supply of the blood through a weakened mucous membrane should not be forgotten. If, through some lesion or weakness in that wall, such bacteria could migrate into the blood what would be likely to happen? Is it not evident that they would most likely reach the liver through the portal circulation and there accumulate around the stores of glycogen? Such we know to be the habits of microorganisms in respect to substances to which they are attracted. We should expect them to set up there a condition of irritation to which the liver, if adapted through natural selection, would respond by giving them all the sugar it could possibly supply. As the muscles would constitute other centers of sugar supply we should suspect them of following the chemotactic pull toward these organs and there also forming centers of irritation. To this irritation we should likewise expect a similar response. Prof. Calkins in referring to Pfeffer's experiments on chemotaxis with a large number of microorganisms tells us that "he also obtained the interesting result that substances which in weak solutions cause a positive reaction, in strong solutions cause a negative one, so that, as in light stimuli, a chemotactic optimum exists toward which the organism constantly strives."[19] If this rule holds of our supposed intestinal bacterium, we should expect it, when thoroughly filled with sugar, to try to drift away from it and thus to land in a condition of surfeit at the kidneys. Of course if overtaken by the way by a superior force of phagocytes they might be engulfed by the latter before getting there. Such of them, however, as did reach the kidneys in safety would have to be guarded against in these organs and in the bladder or they might there set up suppuration. The over-

flow of sugar into the urine would in this way prove to be a source of protection by keeping the bacteria surfeited until either killed or expelled from the body. The continuous supply of sugar up to the last moment of expulsion would keep such bacteria from attacking and destroying the cells in order to appropriate their protoplasm. As glycosuria is a common symptom of fever, poisoning, suffocation, chill, starvation, and severe injuries, it is evident that whatever lowers the vital powers causes it. Whatever others may believe to be the connection between the flow of sugar and the lowered vital power the Darwinian cannot be consistent unless he maintains such flow to be a survival of a fitness in conditions that now threaten and once proved often fatal. There must be great danger to life which the presence of this sugar averts. Is it a weakening of the resisting power of the intestinal walls and a migration into the circulation of some kind of bacteria? Consistency demands such an assumption. But this will force us to the conclusion that the kind of bacteria we must suspect are exceedingly common ones. These symptoms are of such frequent occurrence and are found in so many kinds of animals that the parasite we seek should be well-nigh ubiquitous.

It is customary to look upon the digestive tract as impervious to all forms of bacteria in the absence of some lesion. This view seems to be weakening among many bacteriologists. The condition is, perhaps, best illustrated by Darwin's metaphor in which he says: "Battle within battle must be continually recurring with varying success; and yet in the long run the forces are so nicely balanced that the face of nature remains for long periods of time uniform, though assuredly the merest trifle would give the victory to one organic being over another."[20] Dr. Meltzer tells us that "even only diminished vitality, like in chronic heart- and kidney-diseases, encourages the invasion and settlement of microorganisms in the body."[21] The same author informs us that "The intestine, as will appear from these statements, is regarded as the portal of entry not only of many of the bacteria found in the inflamed peritoneum, but also of some of those present in the pleura, upon the heart valves, and within the organs. This conclusion is based in part upon the behavior of those species which are known to be derived from the intestine, namely, the colon group of bacilli. It has been found that these bacteria wander through the intestinal walls with great regularity where lesions of the intestinal mucosa exist. * * * The occurrence of the colon bacilli in the organs is frequently unassociated with any lesion referable to their presence."[22] He further informs us that the colon bacilli is the most frequent invader of the circulation, and next to it, as a cause of "terminal infections," comes the streptococci. McFarland states that "Beco is of the opinion that, without any apparent lesion of the intestine, bacteria—*Bacillus coli*—escape from it into the blood during life."[23] Herter states that "the colon organisms probably often pass temporarily from the digestive tract by way of the blood to the kidney."[24] As regards the ubiquity of these organisms Roger says that "the colon bacillus is a very prevalent microorganism, perhaps the most widely distributed of all. It is found in the air, soil, and water, and it is constantly met with in the alimentary canal of men and animals, in the mouth, in the stomach, and particularly in the intestine. When this microbe attains virulence, it produces very various lesions."[25] As regards the acquiring of virulence referred to by Roger, Dr. Theobald Smith has this to say: "One of the most important of these groups consists of derivatives of the colon bacillus, which produce epizootics among swine, guinea-pigs, field-mice; and spermophiles, which have been found associated with disease in horses, cattle, and certain birds; with pseudotuberculosis in certain other species, and to which the *B. icteroides* of Sanarelli and perhaps some forms belong which produce disease in the human subject, and which have been variously classed as paracolon bacilli and paratyphoid bacilli. Outbreaks of meat-poisoning in European countries, characterized by gastrointestinal disturbance, are most likely due to this group of organisms, which are introduced into the body in raw meat. The typhoid bacillus is probably a more highly modified offshoot of this same stock."[26] It is evident that, however harmless the average medical man may consider the colon bacillus to be, the bacteriologists deem it far from being a harmless organism. It seems to meet the requirements of the hypothesis which is sought to be formulated in this paper, better than any other that can be found. As regards its affinity toward sugar Dr. A. W. Peckham has this to say about it: "When the members of the colon group are cultivated under circumstances favorable to the development of both the function of fermentation and that of proteolysis, fermentation invariably takes precedence and no evidence of proteolysis is manifested until after fermentation has ceased."[27] Here then is evidence as to the special favor in which this class of organisms holds sugar. So long as they can secure it they let proteid alone. Neither egg nor meat is attacked until the last of the sugar has disappeared. When inhabiting the intestine of a free user of farinaceous food they are always abundantly supplied. When the host they have chosen uses large quantities of fish, flesh, and fowl, with a minimum of bread and potatoes as soon as all of the carbohydrate is converted into sugar and absorbed into the circulation they are left to change their natures or allow their chemotactic power to direct them into the blood where sugar can always be found. Saundby rightly declares that "Insufficient attention has been paid to the possibility of diabetes having, in some cases, a microbic origin. Charron and Carnot have proved that it is possible to render a dog diabetic by injecting infective fluids (*Bacillus coli*, *B. pyocyaneus*, and streptococci) into the pancreatic duct."[28]

Here we find that the colon bacillus in conjunction with some others has actually produced diabetes. Now we naturally ask whether any form of glycosuria ever arises that is not due to one, two, or all three of these quite common denizens of the alimentary canal? Flexner tells us that the frequent occurrence of the colon bacillus in combination with the pyogenic cocci is a matter of considerable importance, and under such circumstances these microorganisms may come to have greater significance."[29] There are some symptoms of diabetes that would appear to indicate a partnership between the pyogenetic cocci and the colon bacilli. We find a union of such a character between the former and the tubercle as well as the typhoid bacilli. But whether the colon bacilli are alone responsible or the responsibility is shared with other organisms, the fact remains that the explanation of the symptoms can more satisfactorily be made with their introduction into the problem than without it. If poisonings, injuries, chillings, and the like lower the vital forces sufficiently to permit of their chemotactic power to act and to carry them into the circulation at a point from which they are likely to reach the liver and muscles, we have all the necessary conditions for a transient glycosuria. If, in a person consuming an excess of proteid food, a severe injury of any kind

lowers the vital forces, then we have the conditions for a case of severe diabetes mellitus. In total ablation of the pancreas we have a severe injury at the very part from which a raid on the liver glycogen could most easily be made. In *Chemical Abstracts,* of the American Chemical Association, appears the following statement concerning some experiments made by Prof. Pflüger of Bonn: "If the duodenum be extirpated in the neighborhood of the pancreas, and the pancreas be kept intact, diabetes is caused, which leads to death. When the mesentery between the duodenum and pancreas is ligatured, diabetes is produced. In the latter operations, the nutrition of the pancreas is not interfered with."[30] The operations were performed on frogs. It would appear from this that the sole essentials in the production of experimental diabetes are impairment of digestion within the duodenum and a lesion which lowers vital resistance sufficiently to permit of the colon bacilli following their natural tropism. It occurs when the pancreas is intact and unimpaired and it occurs when that organ is removed. In cold-blooded animals the removal of the liver at the same time as the pancreas is totally extirpated fails to produce glycosuria.[31] With the liver gone the immediate source of glycogen is removed and no center of chemotaxis is found. Add to this the fact that "Lepine and Boulud state that the blood of a dog recently rendered diabetic by extirpation of its pancreas can produce glycosuria when introduced into the tissues of other animals."[31] If artificial diabetes is unassociated with an infection this result is unexplainable. If the ablation of the pancreas interfered with duodenal nutrition and permitted a migration of microbes into the circulation then it is easy to see just why injecting the blood of the diabetic dog into another animal should infect the latter and produce a glycosuria. Another feature of this that is likely to be overlooked unless special attention is called to it, is the fact that in this injected blood would be found a selected strain of the bacteria responsible for this effect. All parasites that were least adapted to life in the circulation and least prepared to contest their ground with the phagocytes would be dead. Those left alive would be of a kind that to some degree would be capable of holding their own in the new struggle for existence that had arisen in their lives. If there is anything to the hypothesis that our facts seem to sustain, then every incursion of colon bacilli into the blood stream would lead to the production of a variety capable of holding their own among the new conditions. With the kidneys at work drawing off some of the sugar and their own negative chemotaxis carrying them away from its source we should expect their expulsion in the urine. Being facultative parasites they could easily find opportunities to live in the outside environment until chance events carried them once more into a digestive tract. As the progeny of these would hold the heritage of resistance acquired in the blood we would expect them to be more strongly attracted toward the repeating of the blood experience. Theobald Smith has asked the question: "How far does nature utilize animals as a workshop for preparing bacteria to act in a pathogenic rôle upon the human race?"[32] The non-Darwinian may have any sort of theory or no theory as regards how the microbes of typhoid fever came to be so pathogenic, but the Darwinian, who consistently follows the logic of his faith, must confess that he is constrained by his belief in an orderly nature toward placing them among the list of derivatives of the colon bacilli. In just such a manner as we here indicate the typhoid bacillus was probably selected. Its virulence was part of its favorable variation. Favorable, of course, for it and not for its host. It survived by being expelled through the kidneys. It was the surviving ones that perpetuated the strain. Every passage through a human being killed off more and more of the least adapted to life in the circulation and saved such as had increased adaptations. This round of selective action is still going on, and the typhoid organism is becoming better and better fitted for the fight against our bacteriolysins and our phagocytes. But what has happened to it is probably now happening to the sugar consuming members of the colon group. Diabetics are straining off and killing those unfit to cope with their resisting forces while expelling the adapted, by way of the urine, to renew the fight upon others on a coming day. Those that live are the ones with the strongest tendency to invade the circulation, to attack the liver and the muscles at the point where dextrose is thrown off, and to escape again by way of the kidneys as soon as they have completed a cycle of existence that may be becoming established as a permanent character of their being. That the muscles as well as the liver are points of special attack we have inferred *a priori,* but this point has also been found to agree with fact. Von Noorden says: "There seems to be something (in diabetes) which destroys the protoplasm of the muscles and energetically opposes its being built up afresh, in spite of an abundant supply of protein and calories in the food."[33] We might here add, also in spite of the power to utilize both protein and calories. The former is generally conceded but the latter doubted or denied. Bunge tells us that "Kulz has shown that, even in severe cases of diabetes, there is a smaller amount of sugar in the urine than would correspond to the carbohydrates of the food."[34] Wells assures us that there is plenty of evidence of the fact that sugar is oxidized, within the body of those suffering from diabetes, as far, at least, as glycuronic acid.[35] Von Noorden supplements this evidence by informing us that "glycuronic acid given by the mouth becomes oxidized, even in severe diabetes."[36] When we add to this the statement that "a patient who is excreting sugar on a carbohydrate-free diet may climb a mountain or do other severe work which requires normally the burning up of 80 to 100 grams of carbohydrate, and yet continue to excrete nearly or quite as much sugar as he did before,"[37] we are forced to believe that there is no failure of the physiological functions. The trouble is due to some exogenous derived irritant that is stimulating the body, and the excess of activity is made in order to get rid of it. What could possibly attack and weaken the muscle cells except microbes? It is evidently not lack of food, or they could not keep up work under the conditions here referred to with such a drain of sugar accompanying this work. Bunge says that "as the bulk of the sugar is normally decomposed in the muscles, it seems probable that diabetes may fundamentally be due to a disturbance of the chemical processes of muscle."[38] Very likely that is just what it is, but the disturbance is not one in which a physiological process has brought about a pathological condition. The machinery is disturbed by the presence of something not of its own making. The liver and the muscles seem as if they might be the seat of the irritant. They are wasting their accumulations of stored glycogen with as much apparent determination as when hard work is being done. But while the liver and the muscles seem to bear the brunt of the attack there is very little of the body that escapes some de-

gree of damage. Just as typhoid microbes produce lesions in every conceivable part of the body, so diabetes can show its corresponding set of lesions that bear an exceedingly close analogy to the former. The form and tests for the *Bacillus typhosus* seem no nearer like those for *Bacillus coli* than do the terminal lesions of typhoid fever seem to resemble those of diabetes. The analogy when followed through is very striking, but no more striking than it ought to be if the two diseases are of kindred development. Both produce arthritic troubles or are accompanied by such troubles. Both are associated with arteriosclerosis. Both associate themselves with streptococci. Both tend to produce or encourage the production of boils and erysipelas of the skin. In both the bones are attacked and injured. In both the brain and spinal cord are made liable to inflammations. In both the kidneys are endangered. In both there is cardiac enfeeblement. Both produce conditions that lead toward gangrene or fatty degenerations. Both have mild and both severe forms. To read Dr. Keen's "Surgical Complications and Sequels of Typhoid Fever" and to compare what he there tells us with the record of the complications of diabetes, as given by von Noorden, Pavy, and other writers upon this subject, is to discover a good deal of sameness that is rather interesting. Whether or not they are both contagious is not a settled matter. Naturally there would be a tendency among pathologists to minimize the force of all evidence bearing in this direction, but future experiments will settle it. As soon as the pre-Darwinian bias is fully overcome and the hypothesis of infection gets fair consideration we may find that there has actually developed, through natural selection, a specific strain of colon bacilli responsible for the cases of permanent and severe glycosuria. It cannot yet be very pronounced, or it seems as if it ought to have been detected. Osler informs us that "Schmidt first drew attention to the possibility of diabetes being contagious. Out of his series of 2,320 cases he believed that twenty-six instances were the result of contagion. In the majority of the cases the wife contracted the disease later than the husband."[39] Saundby informs us that Dreyfus, Gaucher, Labbe, Letulle, Schmitz, and Rendu have all thought that diabetes might be contagious.[40] Drs. Fitz and Joslin have reported a case of a servant in Massachusetts who was attacked by diabetes after waiting on a mistress who suffered from the disease.[41] Oppler and Kulz report 900 cases of diabetes with nine married couples among them. They collected the histories of 4,389 cases from other physicians and among these were forty-seven married couples.[42] Senator examined 770 cases and among them found nine couples in which both husband and wife were diabetics.[43] Boisumean reports six couples. In these nine and in a large number of other cases of married couples having this disease that he studied, he had found several in which, following the remarriage of the diabetic widow or widower, the new spouse was attacked.[44] If these are all mere coincidences, then it would seem as if the law of probabilities must be suspended for their sakes. It is evident that the proportions to the totals are too great to obey this law. The subject is one that needs careful experimental and statistical attention. The few facts obtainable point strongly toward contagion.

There is one more important symptom of diabetes that is not often referred to but that deserves careful attention. It is that of the peculiar distribution of glycogen in the body during the disease. Of it von Noorden says: "We lack the biological explanation as to why certain cells retain this function, and even exert it more actively than before, while the proper organs for the storage of glycogen have lost it."[45] Viewed as a perversion of function instead of as a beneficent arrangement of our physiological forces for the preservation of the body it is mysterious and meaningless. Viewed as a survival in past struggles for existence the mystery disappears, and it stands forth as a beautiful adaptation of nature for our preservation in the face of threatening danger. Howell informs us that glycogen occurs "in all the tissues of the embryo during the period of most active growth."[46] Tigerstadt states that glycogen "is a constituent of embryonic tissues especially, and all others in which an active cell formation is taking place."[47] Wherever unusually heavy work has to be done, cell growth has to be looked after, and protection in grave danger is needed, there we find glycogen. It constitutes the most quickly available of the accumulated stores of capital for the body. Lusk tells us that "an active organ like the heart maintains its normal glycogen content even after 15 days of starvation."[48] Other organs can be permitted to lose it early, and with safety to the body, but not so the heart. It must be supplied with this source of power till the very last. When a nation is attacked by a foreign foe its capital must be wasted in fighting the foe; but however much the waste may be at the seat of war there must be an accumulation of capital or munitions of war at such points in the country as such capital may be needed to save the life of the nation. The heart and other vital centers must be protracted whether less vital ones are or not. Every animal in which no such protection occurs must, in time, be weeded out. Flutterer informs us that in diabetes masses of glycogen "resembling an embolic process" are found in the cerebral capillaries.[49] Saundby tells us that "glycogen is present in large quantities in the medulla oblongata and the sheaths of the vessels of the cortex" in all cases of diabetes.[50] Wells states that "it is in diabetes, however, that the most marked accumulations of glycogen are found, the granules frequently fusing in the (leucocyte) cells into droplets larger than the nucleus; when dissolved out in ordinary microscopic preparations, the clear round space left is exactly like the space left by a fat-droplet, except that the margins show a tendency to take the basic stain for some unknown reason. In even the most extreme cases, however, the nucleus is well preserved. Glycogen is found particularly in the epithelium of Henle's tubules, in heart muscle, and in the leucocytes."[51] The most reasonable explanation that can be advanced for such a distribution is that these organs all need it as a protection against the attacks of a sugar-using parasite. The renal cells require it because the route of expulsion is by the way of the kidneys. They are thus laid open to a dangerous attack of a pyogenic organism. By this glycogen being present they can defend their protoplasm by supplying sugar and they can also use it as a source of strength. The leucocytes require it because of their phagocytic function. Without it they would be subject to wholesale destruction through the direct attack upon their protoplasm. The cerebrum requires it for reasons of a similar kind that must be obvious to the reader. It is interesting, in this connection, to know that the attack of streptococci upon the system is met by the phagocytes in a precisely similar manner although it is less pronounced. Is the failure of its being so pronounced due to the fact that streptococci are less sugar loving than the

colon organisms? Locke declares that "no septic condition of any severity can be present without a positive reaction" that shows the accumulation within the leucocytes of glycogen.[51]

In our first paper we referred to the new potato cure for diabetes, but did not mention the fact that oatmeal had likewise been used with the same object in view. The reader is probably prepared by this time to explain, on the basis of the hypothesis here proposed, just how the potato and the oatmeal are likely to prove beneficial. They are slowly hydrolyzed into sugar and thus keep up a supply of that substance within the intestinal canal. While this can have no effect upon the parasites already in the blood, it can lessen the supply of new recruits there and, as phagocytosis and kidney activity may be lessening the numbers present in the circulation, this may be the explanation of the change. Dr. James B. Herrick of Chicago, in a recent communication, in reference to the oatmeal cure has this to say: "Explanations as to how this is brought about are far from satisfactory. The carbohydrate that may be compared to a poison for some mild diabetics has a helpful effect on the severer forms, in which forms it would seem to have its harmful influence counteracted by some substance, perhaps the acid bodies, and these substances in turn, also toxic, have their baneful effects neutralized by the carbohydrate, *i.e.* they seem mutually antagonistic or antidotal." The same author declares regarding his own experience with the milder forms that "so far, however, I have seen no evil result from the use of this diet, even in the milder cases that von Noorden classes as unsuitable for this plan of treatment."[52] Here again we meet mystery on mystery by the attempt at explaining diabetes as due to a normal function run mad. Take it as a plain case of infection and all mystery disappears. We need no multiplication of theories on theories, like the piling of Pelion on Ossa, when this simple, common sense hypothesis of infection is provisionally adopted. We find no poisons needed to neutralize poisons, and are not compelled to acknowledge that our own explanations are far from satisfactory. We may need antiseptics to help the carbohydrate diet in lowering the chemotaxis of the invading organisms. Dr. W. Tibbals, not long ago reported that he had found that the use of creosote by his patients enabled them to consume carbohydrates with a lessened outpour of sugar in the urine. He also found that iodoform, salicylic acid, aspirin, and benzosol had a similar effect.[53] Dr. Herrick may not be able to see that the antiseptics act in a similar manner to his oatmeal and that both lines of treatment are equally sound. Neither are cures. Both are palliatives because both check the natural tropism of a parasite. No hypothesis hitherto advanced has ever been able to explain, in an apparently satisfactory manner, so many of the symptoms of diabetes. No other corresponds so well with the known distribution of the disease. Of course it is impossible to be scientifically sure that it is right until experimentally demonstrated. It may be sneeringly referred to as "mere speculation" or "simply guesswork," but it is the kind of speculation and kind of guesswork that causes our courts to commit murderers to the gallows. It is no more —no less—than circumstantial evidence. This is the evidence of inductive science. A murderer or a burglar when brought before our courts is tested by this kind of evidence as regards their guilt or innocence. It differs very materially from mere suspicion, but it is by no means perfect. Until the murderer has confessed or proven an alibi there is room for honest doubt. Those least capable of weighing the evidence will have the greatest cause to doubt where it has been carefully put together. In the case of the parasite here charged with being the cause of diabetes it remains for expert bacteriologists to show cause for a nonconviction by the medical jury before whom these facts have been placed. Can they prove an alibi or will they bring the clinching evidence of its having been caught in the very act? Time alone can tell.

SYMPTOMATOLOGY OF RECURRENT AND ABDUCTOR PARALYSIS OF THE LARYNX.*

By CLARENCE C. RICE, M.D.,

NEW YORK.

The division of this most interesting subject, which has been allotted to me, would at first sight seem a less difficult task than that of the gentlemen who have just read their admirable papers; but when it is appreciated that several varieties of either spasm or paralysis of the vocal bands may coexist, the tabulating of an exact classification of symptoms is not an easy one. It is desirable to select the commonest forms of paralysis of the laryngeal muscles, and give their usual appearances and symptoms rather than to complicate the description by stating the symptomatology of a combination of conditions. A discouraging amount of literature has been written upon the subject of paralysis of the muscles of the larynx, discouraging because we have often found it confusing; and it has been a relief to write, for the most part, from our own observations.

Let us, therefore, endeavor to portray a picture of the clinical phenomena which are present in paralysis of the several muscles and groups of muscles of the larynx. It seems desirable to present the subject of symptomatology under two grand heads or divisions, namely, first, the symptoms, laryngeal and general, of the several temporary disturbances in the efficiency of the laryngeal muscles, disturbances not caused by grave or permanent pathological conditions of the nerve centers, but by injuries inflicted either upon the peripheral nerve filaments or upon the muscular tissue itself; the so-called "myopathic" disturbances, occurring in the various forms of catarrhal laryngitis; the acute and the chronic, either of the moist or dry variety, and the "traumatic" type of laryngitis, a name properly used in describing the crippled vocal conditions of singers, and professional people generally. We suggest this as the first division of our subject, and since it has not been asked of us to describe the impairment of efficiency of the anterior muscle, which is supplied by the superior laryngeal nerve, we must first speak of the laryngeal image and symptoms which are exhibited in paralysis of the internal and tranverse muscles. I should like to be permitted to use the term "transverse" for the arytenoideus muscle; "internal" for the thyro-arytenoideus; "lateral" for the large adductor, and "posterior" for the solitary abductor.

The second division of the subject deals, first, with the symptomatology of paralysis of the large adductor, second, with that of the abductor of the vocal cords and, third, with that of total paralysis of the recurrent nerve.

We suggest that it will simplify matters if we keep this division widely apart in our minds, because in the first or "myopathic" class, the laryngeal image of disturbance is constantly changing, and may present abnormal laryngoscopic appearances for but a short time, because the tone of the muscles is apt to be rapidly restored by rest and intelligent remedies. It is of interest to radically separate the fatigued appearances of the internal and transverse muscles from the widely different exhibition presented by a permanently disabled lateral abductor, caused by lesion of nerve trunks; a paralysis in the full sense of the term, a condition usually not to be improved, because the lesion is permanent and often progressive.

In our first division, paralysis of the internal muscle is by far the most common. We can say that it is nearly always one of the manifestations of a severe grade of laryngitis. The college boy attending a single game of football, can so abuse his vocal apparatus, as to become aphonic the following day, and his vocal bands present the characteristic elliptic opening, extending from the vocal process to the anterior commissure. The picture is familiar to us all. The degree of hoarseness or loss of voice depends upon the diameter of the ellipse, as well as upon the accompanying general inflammatory conditions. The history of the case is so simple as to make the diagnosis itself. The disturbance in these acute cases is nearly always bilateral. If such injury as shouting and screaming is inflicted upon a perfectly healthy larynx, the vocal bands of the aphonic patient will next day present the elliptical opening, and the margins of the bands will be markedly concave, but there will not necessarily be any accompaniment of congestion and swelling. In some cases the wider separation of the vocal bands, at attempts of phonation, would indicate that the lateral adductors had also been injured by the unusual strain. When such injury as we have described is imposed upon a larynx which has been the seat of a chronic catarrhal condition, especially of the dry variety, congestion and, perhaps, thickening of the bands will be associated with the concaved margins of the vocal bands.

Again, we sometimes see cases where in addition to the elliptical concavity symptomatic of paresis of the internal tensors, we find the bands very strongly abducted; bands not in the cadaveric position of recurrent paralysis, but resembling the picture, which theoretically should indicate a combination of internal and lateral paralysis. (Fig. 1.) The patient in these cases is entirely without voice. I have seen vocal cords completely abducted to the sides of the larynx, and concave throughout, in cases of chronic laryngeal catarrh, associated with a far-advanced atrophic condition of the nose, pharynx, and larynx. I recall no such cases in private practice; they have been in dispensary patients, most commonly in women, and, strange to say, in fat women, who have usually been cooks. I recall two cases, and in both there was a severe dry catarrh of the larynx and trachea. The lesion in these cases I have always supposed to be peripheral, due to inflammation of nerve terminations. Both of these cases made a fair recovery.

We have seen unilateral paralysis of the internal muscle, as evidenced by a moderate concavity of one vocal band, in chronic laryngitis where pathological injury was greater on one side than the other. The left cord or its nerve or muscular supply is undoubtedly the weaker of the two. It is not unusual to see concavity of that band with some degree of failure of adduction, associated with such singers' injuries as congestion, general thickening, and perhaps a localized nodule. (Fig. 2.) This impairment of muscular tone is not so easily repaired as in the acute cases, where both internal muscles are temporarily enfeebled, because continued abuse has produced a chronic impairment of muscular power.

The symptoms of all disturbances of the internal muscle, whether unilateral or bilateral, aside from the well-known laryngeal image, are those of some degree of vocal disturbance, from simple hoarseness, to entire loss of voice, depending upon the degree of separation of the cords during phonation. Even if the power of the internal muscles should remain

*Read before the American Laryngological Association at the thirtieth annual session, held in Montreal, May, 1908.

permanently impaired, the compensatory power of the other adductors would pretty largely approximate the cords sufficiently for the ordinary speaking voice; but as some of the fibers of the internal muscle are attached to the edge of the vocal band, and as they very nicely regulate the tension of the cord,

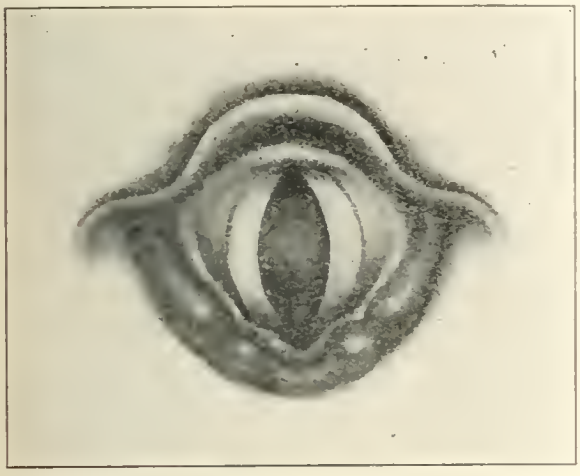

Fig. 1.—Combination of bilateral internal and lateral paralysis, during phonation.

frequent disturbances of this kind will do great and lasting injury to the singing voice. The vocal bands are the tendons of the internal muscles, and when these muscles are paralyzed the bands become more narrow and humped up. The singing voice is frequently impaired when the laryngeal mirror shows no apparent loss of power of any of the laryngeal muscles, and in such cases we are led to conclude that the fault is due to weakness of that portion of the internal muscle which is attached to the edge of the cords. Paralysis of the internal muscles is sometimes called "paralysis of the vocal cords themselves," in contradistinction to all other forms of paralysis.

Paralysis of the short transverse or arytenoideus muscle is much less frequently seen than that of the internal; rarely, I believe, in ordinary catarrhal laryngitis, although the posterior triangular aperture may, frequently, to a slight degree, accompany impairment of the "internal" muscle. Where the triangle is large and charateristic, it has been my experience to find it in cases of local disease of or near the arytenoid cartilages, such as tubercular infiltration of the posterior commissure. The diagnosis of this condition, if it exists alone, is very easy, and the degree of impairment of voice is in proportion to its degree and to other disturbances of the larynx. The speaking voice is almost normal, but in singing there is phonatory leakage, and the voice becomes quickly fatigued. It is interesting in cases of paralysis of the transverse muscle, to notice, with the laryngeal mirror, the jerky motions of the arytenoid cartilages during phonation. I suppose this is because this muscle often receives its nerve supply from two sources. I have not frequently seen this triangular paralysis associated with the concavity of the cords which indicates inaction of the internal muscle, and it has been our experience that paralysis of the transverse muscle is much more frequently associated with that of the anterior or thyrocricoid. It is not necessary to dwell longer upon this division of our subject, because the laryngeal picture is easy to comprehend.

It is much more difficult to give an intelligent symptomatology of the second division of our subject, which in reality is the entire topic of our discussion to-day. "The symptoms of recurrent and abductor paralysis of the larynx," is the text printed on our programs.

It seems to us unfortunate that the word "recurrent" has been employed in describing the nerve supply of the larynx. Why should not the names superior and inferior laryngeal nerves be sufficient? This nomenclature would be less confusing.

It will simplify our position if we state that there are practically but two forms of laryngeal paralysis, exclusive of those which we have described in the early part of our paper, and they are: first, "abductor paralysis;" and second, "recurrent laryngeal paralysis;" and we should perhaps add to these, those cases of adductor spasm which simulate abductor paralysis. There may possibly be a few cases of solitary adductor paralysis on record, but such a high authority as Semon, says not. Such a condition would show vocal bands abducted to the sides of the larynx, would produce complete aphonia, and a hoarse low-pitched noise when the patient coughed or laughed.

Theoretically, there should be a time in cases of irritation of the recurrent nerve, when a laryngeal picture of spasm of the powerful adductors is in evidence. When we consider that there are three and even four strong adductors of the bands to the one solitary abductor, we may reasonably conclude that irritation of nerve centers or trunks, insufficient to cause entire loss of muscular power, would naturally produce approximation, rather than separation of the bands. This picture would simulate that of paralysis of the abductors. Let us for a moment consider the points of symptomatology in spasm of the adductors and paralysis of the abducting power of the bands. This is fitting, because when irritative spasm has been succeeded by true paralysis, it is generally conceded that the abductor fibers are the first to give way. The anatomical reason for this has already been ably stated in the papers preceding me. We believe it can be truthfully said, then, that, so far as the laryngeal image is concerned, there are three stages in the course of nerve and muscular impairment. First, adductor spasm; second, abductor paralysis; and third, total inaction of all the muscles of the larynx supplied by the inferior laryngeal nerve, that is recurrent paralysis, or laryngo hemiplegia. The condition of

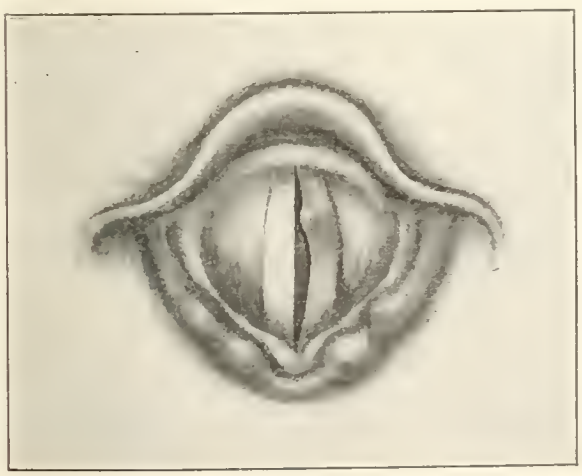

Fig. 2.—Paralysis of left internal, with congestion and nodule of cord.

spasm of any set of muscles is not a permanent one, as is that of paralysis, but occurs at periods of irregular intervals. It is possible that some of the cases of so-called laryngeal chorea associated with general chorea, vertigo, and stridor are really cases of adductor spasm, which eventuate later in true paralysis. It does not belong to this paper to speak

of functional hysterical spasm which may, by extreme and prolonged adduction, produce unconsciousness for a brief period, until relaxation ensues. We read, too, of rare cases where patients make most unusual noises associated with forcible closure of the glottis.

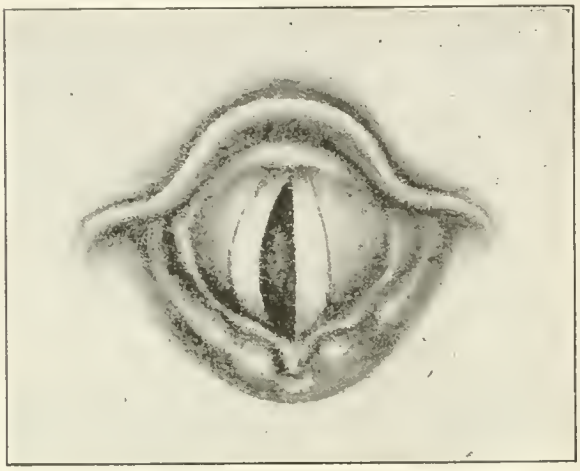

Fig. 3.—Unilateral paralysis of left posterior muscle, during respiration

It is difficult to give a precise picture of the differential laryngeal images seen in adductor spasm and in abductor paralysis. Theoretically the vocal bands should be much more taut in adductor spasm. We use the term adductor spasm rather than laryngeal spasm, since irritation of the nerves, which should produce both adductor and abductor spasm, only accentuates the action of the adductors, owing to their greater number and strength. It is well to bear in mind that adductor spasm of the vocal cords may produce what is called laryngeal crisis, and give such symptoms as the forceful cough seen in whooping cough. Irregular and intermittent adduction of the bands will produce irregular inspiratory dyspnea, and many different pitches in stridulous breathing, but these symptoms are all temporary, in contradistinction to those of a permanent abductor paralysis.

If the spasm is severe it is said that the adduction may be so forcible as to produce overlapping of the vocal bands, and pain in the larynx like that of cramp. If spasm of the adductors continued for any length of time, stenosis would be so complete as to destroy life.

Theoretically, what has been said regarding the symptoms of spasm of adduction may be of importance, but clinically we know little of such cases.

If due to functional causes, the symptoms soon disappear; if caused by actual nerve lesion, the spasm is succeeded by abductor and recurrent paralysis. A symptom which is sometimes of value as indicating central involvement of the inhibitory center is a persistently rapid pulse—and this with normal heart and temperature.

We must next call your attention to the symptoms of abductor or "posticus" paralysis; that of the great inspiratory muscles, the glottic openers, which yield to injury sooner than the opposing lateral muscle. It is perhaps well to remember a point which we fear we have repeated many times, and that is that a lesion which eventually produces recurrent paralysis may first cause paralysis of abduction alone. Since central lesions are more rare than those affecting the nerve trunks, unilateral paralysis of the abductor and its consequent symptoms are more common than those of bilateral paralysis. Not much time is needed to describe the laryngeal picture of unilateral paralysis of the abductor, nor its objective symptoms. The affected cord is seen in the median line, even in deep inspiration; phonation should not be markedly interfered with, and in unilateral cases the normal abduction of the other band should give ample breathing space.

Unilateral abductor paralysis rarely gives symptoms to attract the attention of the patient or of the physician,—unless the abductor paralysis has been preceded by spasm and abnormal phonatory symptoms. The affected vocal band remains in the median line during inspiration, because the three adductors are, at the commencement of the nerve injury, in their full integrity. (Fig. 3.) Breathing may be slightly affected during great exertion. The voice is so little affected that if our diagnosis was correct, we recall the case of a singer who retained a church position, never knowing that he had one vocal band which remained immovable in the median line. While the voice may be at times normal, it is apt to be uncertain, and break in pitch, because one cord may lie at a lower level than its fellow. In sopranos and tenors singing would be almost impossible. The voice would become more and more uncertain, because the tendency of an abductor paralysis is towards a recurrent disability. It is quite possible that many cases of unilateral paralysis escape the notice of the laryngologist, because they often give no marked symptoms until a laryngo hemiplegia is present. It is for that reason that most observers believe that unilateral recurrent paralysis is more frequent than unilateral posticus paralysis. Much more has been written about the symptoms of bilateral abductor paralysis, because they are so much more noticeable and dangerous than in the unilateral lesion. Semon says that in bilateral posticus paralysis, the position of the bands may pass through two stages. First, they are in the cadaveric position of recurrent paralysis, but later, if the adductors recover their tone, the paralyzed cord openers, which remain incompetent, leave the bands in the median line. When we remember that the abductor muscle is solitary, and opposed by several, and by more powerful antagonistic muscles, it is easily understood why the bands remain immovable in the median line. The glottis presents the appearance

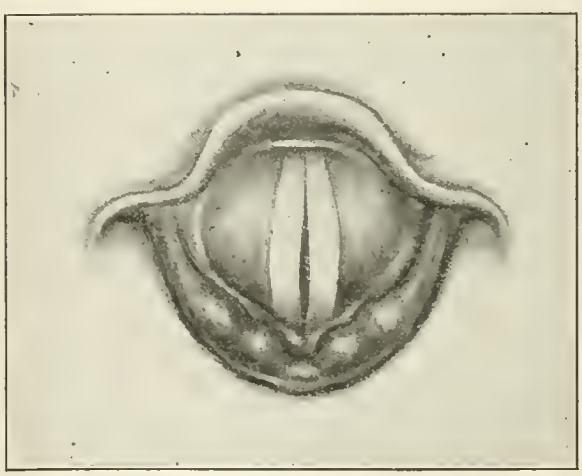

Fig. 4.—Bilateral paralysis of posterior muscles, during respiration.

of an anteroposterior slit between the bands. The cords are blown slightly apart during expiration; and if the adduction is extreme, the inspiration may be prolonged—high-pitched and stridulous. (Fig. 4.) The air current may actually turn the edges of the bands downward as it passes through. In posticus

paralysis, dyspnea comes on by degrees, and may steadily increase, and is aggravated by physical exertion and mental excitement. Cases are recorded where the onset is so sudden that the patient is awakened in the night struggling for breath. In children in dyspnea is much more distressing, be-

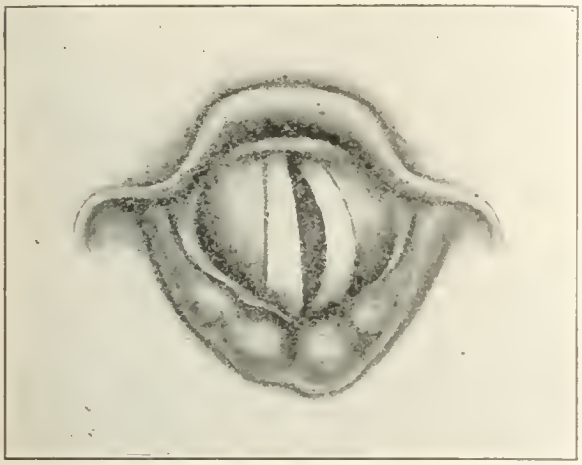

Fig 5.—Complete left recurrent paralysis, during phonation.

cause the larynx is smaller, and breathing is rendered more difficult by crying and struggling. In children there may be noticed a disproportion in length of time between the acts of inspiration and expiration. Inspiration requires much more time than usual, because of the glottic obstruction. Expiration relatively requires less time. The voice may be nearly normal, but is apt to be breathy and uncertain. Confusion in the diagnosis of paralysis of any one group of laryngeal muscles of the larynx, is rendered easy by the spasmodic contraction of any opposing group which are at the same time responding to nerve irritation. Some writers speak of the offensive breath in cases of abductor paralysis, which they believe to be due to the decomposition of laryngeal secretions, by reason of improper drainage and ventilation.

It is remarkable through how small an aperture a quiet, calm patient may breathe without showing apparent dyspnea. We have sen cases in which the inspiratory current actually turned the vocal bands inward, as it sucked downwards between the vocal cords. This in the case of bilateral abductor paralysis. We have seen recently a case of tubercular swelling of the larynx, in which hardly any breathing space could be seen, and the patient complained not at all of respiratory difficulty, but this is a digression.

The symptoms of a solitary adductor or "lateral" paralysis, as it may well be called, can theoretically be easily stated. This must necessarily be a very rare condition, because the lateral muscle possesses so much vitality that, as we have seen, the posterior is the first to succumb, and a more extensive lesion paralyzes all the muscles supplied by the inferior nerve, and a laryngohemiplegia, not a *lateral* paralysis is the result. But if the fibers of the lateral are alone affected, the vocal band, if the lesion is unilateral, or both bands, if it is bilateral, would be seen to be in about the cadaveric position, during attempts at phonation, for the internal and transverse muscles would probably be competent to draw the bands to this position. In a state of inspiratory and phonatory rest, when the posterior muscle was not in action, the cords would be in the cadaveric position. The essential diagnostic point of time would be during deep and forced inspiration, when the unopposed abductors would draw the bands outwards to the extreme sides of the larynx. If the lesion is one-sided, the affected cord makes a more outward journey than its fellow. But during rest and phonation, the three other adductors are competent to keep the disabled band as near the median line as the cadaveric position, which is the position of a recurrent paralysis. The diagnosis, therefore, must be made during forced inspiration. Theoretically, the margins of the bands would assume a straighter line in lateral paralysis than in recurrent, because the smaller tensors would be still exerting their power, but the voice would be weaker—there would be larger phonatory leakage, because on account of the larger separation of the bands the normal cord would not be able to get so close to its fellow as it does in a one-sided recurrent paralysis; sometimes even coughing is impossible, and the voice is completely lost. The bilateral laryngeal image of a lateral paralysis is almost identical, therefore, with that of a bilateral recurrent paralysis, except at the period of forced inspiration, when there is wider abduction in the former than in the latter. The speaking voice, in all varities of paralysis, commonly improves, because of the marvelous ability of the uninjured muscles to render compensatory aid to the disabled ones. If there was time, we should like to cite examples of such compensatory action, but we have already presented to this association a paper on the subject.

Lastly we must speak of the symptomatology of recurrent paralysis, that is a total paralysis of all the muscles supplied by the inferior laryngeal nerve. This is the form most commonly observed by the laryngologist, because, as has been frequently said, if the other forms, excepting bilateral posterior paralysis precede it, they usually furnish so little evidence of their existence that the nerve lesion has produced a recurrent paralysis by the time the patient consults a physician. The band or bands are in the cadaveric position, and respiration is little affected during rest. (Fig. 5.) In one-sided paralysis, the speaking voice steadily improves, as the sound vocal cord is able to go a longer distance, but the voice at first is lower pitched, uncertain, becomes tired easily, and the nervous patient dreads to use his voice, because of its liability to make ludicrous

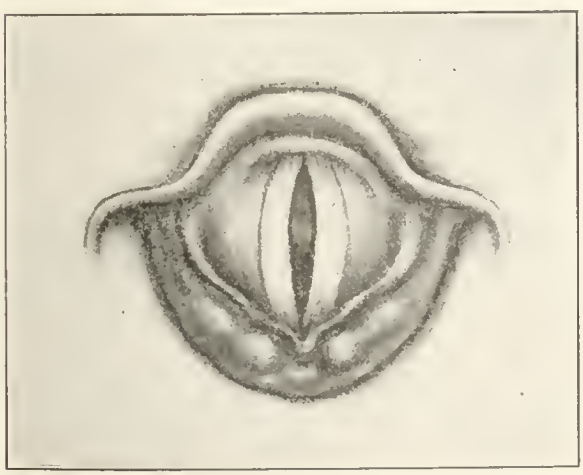

Fig. 6.—Bilateral recurrent paralysis, during phonation.

breaks in pitch. In bilateral recurrent paralysis, there can be no marked dyspnea, but the voice is lost or very breathy and uncertain, and because of nonapproximation of the false cords, the pitch in coughing is lowered, and instead of terminating with a short explosion, it is prolonged, sounding

like a hoarse fog horn, until the phonatory leakage empties the lungs. (Fig. 6.) The sound arytenoid is sometimes pulled in front of the disabled one, and pushes it backwards, and the weaker band sometimes lies at a lower level than the opposite one. Since aneurysm or neoplasms in the neck and upper chest are most frequently the cause of unilateral recurrent paralysis, they themselves sometimes furnish symptoms, which help materially to determine not only whether the laryngeal condition is one of paralysis rather than one of ankylosis, but such symptoms may also differentiate between paralysis and spasm. Watson Williams says a peculiar brassy cough may be one of the earliest symptoms of thoracic aneurysm.

I believe it is not in my task to speak of the differential diagnosis between the forms of paralysis and the immobility of a band by reason of an ankylosed cricoarytenoid joint. As a rule this joint, when affected, shows inflammatory signs, but authors speak of a degenerative change here, which does not affect the gross appearance of these cartilages, but a careful history of the case should make its character plain. Most authors note the fact that in unilateral ankylosis the sound arytenoid is only drawn up to and not in front of the disabled one, and in ankylosis, too, the band is not in any known paralytic position, neither in that of abduction, adduction, nor in the cadaveric position. Theoretically in nonparalytic conditions, the bands are tense, while in paralysis they are limp.

In closing I would say that it is difficult to tabulate any statement of symptoms of the motor neuroses of the larynx, which renders the diagnosis positive without a careful examination with the laryngeal mirror. So far as the voice is affected, there is present every degree of impairment, from slight hoarseness to complete aphonia; a lesion which shows no abnormality in quiet conversation, would be apparent if the patient endeavored to use the voice in a forcible way, or tried to sing. The quality of the voice may even change from day to day, because the compensatory aid given by the unaffected muscles constantly varies in efficiency. In unilateral conditions, it may be stated, as a rule, that the voice shows a gradual and permanent improvement if the vocal cord muscles proper, the internal tensors on the affected side, retain their integrity; but if loss of power here allows the margin of the band to remain concave, there is little hope of vocal improvement. This is an important point in considering the prognosis of voice behavior. A careful study of the conversational pitch from day to day would show whether the impaired muscles were improving in tone. One unaffected lateral muscle can make approximation sufficiently good for ordinary conversation, provided the margin of the affected band is straight and not concave. We do not see so many concave bands, even in unilateral recurrent paralysis, because, I suppose, the anterior muscle is, as a rule, not involved, and so the margin of the band is kept fairly straight and taut. As to dyspnea, there are many degrees of this. It has already been said that if the loss of power develops slowly, and consequently if the respiratory space is but gradually narrowed, the patient accommodates himself, in a remarkable manner, to a larynx almost entirely closed, without showing visible distress. Other symptoms such as vocal fatigue, laryngeal cramps and cough, depend much upon the individual case and upon conditions apart from the neurosis. There are many cases where it will require numerous and most painstaking examinations to determine what muscle or group of muscles are at fault, because perhaps the state of partial paralysis will be masked by a condition of jerky spasm. A weak solution of cocaine sometimes aids, by quieting spasm, and by emphasizing the image of real loss of power. The symptoms of no two cases seem to be exactly similar, and it is most interesting to carefully study the behavior of each.

123 East Nineteenth Street.

MECHANICAL VIBRATION IN THE TREATMENT OF CONSTIPATION AND PELVIC CONDITIONS.*

By MARY L. H. ARNOLD SNOW, M.D.,

NEW YORK.

The progress of the last half century has not only marked an era of advancement in the improvement of therapeutic measures, unparalleled in the history of medical science, but has brought to physical therapeutics long delayed recognition, placing in the hands of the profession a full quiver of practical agents with which to combat disease with greater success and add to the glory of medical science.

Among the many useful measures, mechanical vibration occupies an important place; ancient so far as its governing powers are concerned, but modern in its extensive therapeutic application. Its wide range of usefulness and the low market price of an equipment make it one of the first physical measures to be introduced into the office of the general practitioner. In the treatment of constipation and pelvic conditions alone, it is deserving of recognition.

Mechanical vibration is of great assistance in diagnosis. It often elicits facts that are not revealed by percussion or other methods of investigation. Especially is this true of conditions of the liver, which is frequently found to be in a hypersensitive state; in this case marked tenderness is also often found by vibration below the angle of the right scapula and over the gall-bladder, as well as pain in the dorsal region to the right of the spine, which is readily elicited by means of interrupted spinal vibration, employing a ball vibratode. Vibration with the disk vibratode may also discover marked tenderness over the bowels, especially in the cases of mucous colitis, or other congested viscera may be found markedly sensitive.

For many years the treatment of constipation has been chiefly by drugs which gradually bring about an atonic condition of the intestines, demanding a stimulant to induce action that in time aggravates instead of relieving the condition. Physical measures, on the other hand, particularly the static wave current and mechanical vibration, tone up the nervous, muscular, and secretory functions, and, in connection with the regulation of the liver and digestive functions, soon effect a cure. Vibration has mechanical, chemical, physical, metabolic, and reflex effects. It is an agent whose effects depend much upon the method of application and technique in general. It induces the removal of extravasations, lymph, exudations, and transudations, prevents the formation of adhesions, breaks up slight adhesions, and stimulates the circulatory and lymphatic systems. It improves respiration, stimulates excretion and secretion, relaxes contracted parts, and restores tone to relaxed parts. The following principles should govern its application:

1. The vibration should possess the necessary rapidity and length of stroke demanded to meet

*Read at the II. Congrès International de Physiotherapie, at Rome, Italy, October, 1907.

a given condition, and exerted pressure must be such as to be painless.

2. The rapidity, stroke, pressure, or nonpressure should be governed by the indications and the patient's reactionary resistance.

3. The interruptions when using interrupted vibration should be limited in number to avoid exhaustion in nerve power.

4. The intervals of rest should be three, or even four, times as long as the period of impulse contact to assist in perpetuity and fixedness of the effect.

5. The periods of contact and rest should be rhythmical in the administration of interrupted vibration.

6. Vibratory effects should be applied to aid or promote functional activity of a part without altering the integrity or unfavorably affecting the normal activity of the part.

Mechanical vibration in conjunction with dietary measures, and in some instances exercises directed to the compression of the bowels and liver, is the treatment *par excellence* for constipation. When carefully administered, it is absolutely painless, harmless, and productive of the most gratifying results, and consequently, like many other physical measures, is worthy of a trial by the general practitioner. The quantity, kind, and quality of the food ingested must be regulated, in order that the functions may not be overtaxed and that the food may at the same time be nutritious and not too concentrated.

For infants, in whom constipation is easily cured by the use of mechanical vibration, the mother's milk or the artificial food, which may contain too much fat, should be rectified. Young children are apt to consume too much starchy food, or live on a too exclusive diet. With children vibratory treatment, spinal and abdominal, as well as of the liver and spleen, gives most happy results, and if properly applied is generally agreeable to them. The diet used in general, bulk and nutrition considered, should include the following: Stewed fruits, fresh fruits except bananas and pineapples, rye or coarse bread with much butter, or shredded wheat biscuits, triscuits, or Graham bread, cracked wheat or oatmeal thoroughly cooked, broiled chops or soft-boiled eggs, roasted or broiled beef, lamb, or mutton, or baked or broiled fish, or roasted chicken; spinach, celery, lettuce, beets, fresh string beans, and a baked potato—sweet or Irish. Hot water is to be preferred to tea, coffee, or milk. If the patient is thin, anemic, and weak, a milk and cream mixture—three parts milk and one part cream—is recommended to be taken between meals, a glassful at a time, until a quart of milk is taken daily. Six or eight glasses of water should be taken daily.

The formation of a habit of a fixed time for going to stool is important. In children a low vessel or a low seat of proper dimensions should be provided. The time for going to stool, usually best after breakfast, should be a time relative as Savage so aptly puts it, "to some living habit," as rising. The patient should sit patiently for five minutes at least, but the five minutes should not be used in reading, for nature attends well to but one thing at a time.

The cause of the trouble should first be discovered and remedied if possible, either surgically, if such procedure is indicated, or otherwise. If symptomatic, the treatment of the cause is indicated; if from habit, as from failure to meet Nature's calls, disregard of regularity, reading for a long time when at stool, or a faulty diet, correct the fault. Atonic conditions or disturbances of general nutrition, as well as a pernicious drug habit, demand attention. Chronic invagination of the sigmoid, so often overlooked or treated by surgical measures, may sometimes be effectively relieved by rectal vibration in connection with a corrected diet. If the constipation be due to a fibroid tumor associated with hemorrhage, when an operation can be avoided, employ the .r-ray to check the hemorrhage, then use the wave current to cause contraction and relieve local stasis and give a body vibratory treatment for constipation, the abdominal vibratory treatment for a passive exercise being governed by conditions. The rectal vibration is contraindicated because of the danger of inducing hemorrhage.

If adhesions or spasmodic strictures are present they may be benefited or cured by local vibratory treatment. If an enlarged or retroverted uterus obstructs the passage the constipation can be cured in the majority of cases by using the static wave current with a metal electrode per rectum, in connection with rectal and body vibratory treatment for constipation.

In some nervous diseases, as locomotor ataxia, associated with rectal spasm, constipation may often be relieved by rectal vibratory treatment with a short rectal vibratode. The application should be for about five minutes daily until relieved, but at a higher rate of speed than is employed in the treatment of constipation associated with atony. A cone-shaped vibratode may be used in place of the rectal one where anal spasm alone exists; but great care should be exercised, as sometimes, though rarely, paralysis of the bowels follows dilatation.

The oscillator, a machine giving a vibration and a return vibration, as it were, is sometimes used in treating constipation. A wide belt is applied over the lumbar spine, the liver, and the abdomen, in turn, treatment being regulated at from six to ten millimeters off the center of the revolving eccentric.

The author's technique for vibratory treatment of constipation consists of (1) vibration of the spinal nerves supplying the affected parts, (2) a local vibratory treatment of the liver, spleen, and abdomen. The treatment should be mild at first, with strict adherence to the principles governing the use of pressure, stroke, speed, and regulated frequency, bridging the effect from treatment to treatment, lessening the frequency as improvement permits in all cases. The administrations may be made directly to the skin, or over the under-vest or chemise. The following details of technique are observed: (1) The bladder should be emptied before treatment. (2) If the skin is moist and sticky, dust the surface with a suitable dusting powder. (3) If the abdomen is hypersensitive the application of dry heat by means of a high-power incandescent lamp or otherwise will lessen the sensitiveness.

Contraindications for the employment of mechanical vibration are the presence of cancer or ulcer in the region, and a tendency to hemorrhage. In vibrating the spinal nerve roots, use a hard rubber ball vibratode, and employ a medium stroke and moderate pressure, which should be so graduated as to avoid unpleasant effects. Employ the vibratode between the transverse processes on each side of the spine alternately from above downward, two or three times. Tolerance to pressure over tender spots increases during an administration and during the course of treatment. The pressure, light at first, should be gradually increased. Prolonged pressure inhibits, and is consequently applied over the hypersensitive places. If the whole trouble is in the lower bowel, the lower portion of the spine alone may be vibrated; but in the majority of cases of constipation the liver is at fault, and the patient may have

suffered so long that the health has become generally impaired, in which case we vibrate the spaces corresponding with all the spinal nerves to restore tone.

Boardman Reed locates the center of defecation at the second segment of the lumbar part of the spinal cord opposite the tenth dorsal vertebra. From the sixth to the twelfth dorsal inclusive is the inhibition region of the small intestine, the inhibitory nerve being the splanchnic (Pflüger), while the capillaries contain arterial blood; when this changes to venous the splanchnics are stimulated, and peristalsis is increased. If the nervierigentes are stimulated, contraction of the longitudinal rectal fibers occurs, and the action of the circular fibers is inhibited, even when the hypogastric nerves by which they are supplied are stimulated, which stimulation has "an inhibitory effect on the longitudinal muscles" (Fellner). The vasoconstrictors of the colon come from "between the sixth dorsal and second lumbar segment," and the vasodilators are from the same part of the spinal cord and from the nucleus of the pneumogastrics. The vasoconstrictors of the sigmoid flexure and rectum come from the tenth dorsal to the fourth lumbar" (Reed). The vasodilator fibers for the same arise from "the first to the fourth sacral segments." The vasoconstrictors of the small intestine are "from the sixth dorsal to the second lumbar through the visceral nerves to the solar plexus and then to the blood-vessels of the abdomen, jejunum, and ileum," the dilators of the same rise from "the nucleus of the pneumogastrics and go to the solar plexus" (Reed). Stimuli applied "at long intervals to the nerves act on the vasodilators while tetanizing stimuli act especially on the vasomotors," which are not so easily exhausted.

The liver is vibrated as follows: Posteriorly vibratory friction or percussion is applied from the spine outward following the line in the spaces between the ribs, using a rubber-padded disk vibratode over the organ, and interrupted vibration with moderate pressure and medium stroke is applied over the liver anteriorly, covering the surface about three times. The vasoconstrictors of the portal system are from the third to the twelfth dorsal nerves, inclusive, particularly the fifth, sixth, seventh, and eighth. Contraction of the gall-bladder may be induced by vibratory stimulation of the ninth and tenth dorsal. The solar plexus and lumbar ganglia may be affected by interrupted vibration. Stimulation of the vagus contracts the stomach and pylorus, and induces gastric flow.

Vibration of the abdomen is accomplished with a padded rubber disk vibratode, using a medium stroke. Two methods are employed: The first is to follow from the cecum to the sigmoid. The second is the one preferred, and used by the writer because it is almost always necessary to stimulate the lower part of the bowel first. Begin over the middle segment of the descending colon, use vibratory friction with firm pressure downward and inward six or seven times, gradually approaching the ribs, but each time ending at the sigmoid. Then vibrate the transverse colon, beginning at its middle segment and proceeding from right to left, gradually lengthening the line of advance as the hepatic flexure is approached; then begin midway between the hepatic flexure and the cecum, and vibrate upward, gradually approaching the cecum until the friction is from the cecum to the hepatic flexure. A ball vibratode or the cap shield of some machines is then used from the cecum to the sigmoid to administer an analogue of the cannon-ball massage. The speed and rate of vibration should be slow, because parts containing unstriped fibers, after being stimulated, react "for a long time after the stimulus is withdrawn."

In many of the cases the additional use of internal vibratory treatment is necessary. A soft rubber vibratode (see Fig. 1A), well lubricated, which may be introduced while in motion, is to be preferred. The administration should be for five minutes, using a short stroke and a rate of speed, which will give the maximum width of the loops that are to be formed by the vibration of the vibratode when the operator watches the vibratode before inserting it, as he varies the speed until the desired rate is obtained. These rectal treatments should be given daily until the bowels move naturally. After they have moved for several days successively the rectal treatment should be discontinued or given only occasionally as indicated. In obstinate cases, as from a spasmodic stricture high up, a flexible rubber vibratode 12 or 15 inches long (see Fig 1B) is of service, and is most easily introduced with the patient in the knee-chest position. The duration of the treatment should be from three to five minutes, speed and stroke being as before stated. The rectal tube should be used cautiously if adhesions exist from a former peritonitis. The majority of cases are practically

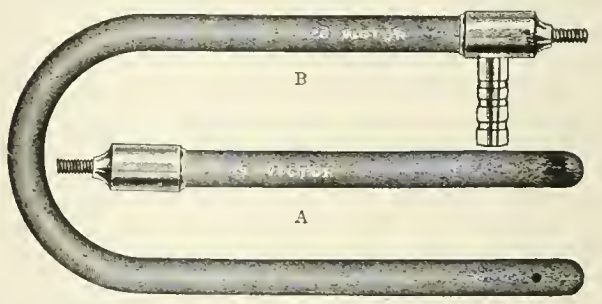

Fig. 1.—The rubber vibratode. A, a short rubber instrument for treating constipation; B, the author's long rubber vibratode for high rectal vibration and for giving high colonic flushings as employed in the treatment of constipation.

cured in about two weeks by this method of treatment.

In severe cases of constipation enemas of from one to three quarts of water, according to the indications of the case, are administered, for which the following method of vibratory flushing has been introduced by the writer. A long hollow flexible rubber vibratode (see Fig. 1B) having a hole in the distal end, and a metal tube at the side of the top of its fitting at the proximal end, to which a tube from a douche bag is attached, is connected to the vibrator. Water is allowed to flow through the tube before it is introduced. Having been smeared with vaseline, it is gradually inserted, vibrating at a slow rate of speed, the patient being in the knee-chest position. When the tube has been inserted a few inches, the water is allowed to flow. The water will be thrown from the opening as from a sprinkler. Gradually increase the speed. After the first pint of water has flowed, gradually lessen the speed and stop the vibrations. Let two or three quarts flow into the bowel, and while the last pint is passing, start the vibrations again and continue them until the tube is withdrawn. Usually one week of vibratory flushing, used after the body vibration as above described, initiates the improvement.

In a few uncomplicated cases of constipation, body vibratory treatment alone is sufficient. This is particularly true during childhood. If the patient

has been long constipated and there is reason to believe that the bowel is lined with impacted feces, a vibratory enema of one to two cupfuls of oil is given, as described below under the treatment of colitis. This is followed the next day by vibratory flushing, as described above. It may be found necessary to repeat this if the patient still gives a history of passing scyballa.

In cases of infantile paralysis associated with constipation, a spinal, liver, spleen, and vibratory treatment will give excellent results, great care being exercised so that too great pressure is not employed. A vacuum cup vibratode is employed for the spinal treatment instead of the ball, as it can be more easily applied in the small intervertebral spaces. Vibratory friction is also employed over the paralyzed parts.

In cases of colitis associated with constipation, most gratifying results are obtained by administering vibratory treatment in connection with a modified von Noorden diet. On the first and third day in the treatment of colitis a high enema of oil is given with long rectal tube (Fig. 1B), previously described for flushing. A little oil is allowed to run through the tube first before introducing it, to prevent colic. Vibration should be mild at first—just sufficient to carry the tube up, except in cases associated with diarrhea, when it is advisable to discontinue it until the oil is all in the bowel, otherwise mild vibration may be continued during the passage of the oil. Disturbances may occur, in which case hot compresses may be used, but I have not found them necessary. Patients may gradually be weaned from the prescribed diet, but it is advisable for them not to depart too early or too suddenly from the dietary régime.

Vibration therapy is indicated in the treatment of contracted muscles arising from various causes, and may be used in the treatment of amenorrhea, dysmenorrhea, inflammatory exudates, endometritis, metritis, oöphoritis, rectal prolapse, certain prostatic conditions, and coccygodynia. In cases of atony, passive congestion, and amenorrhea, vibrate the lower portion of the spine in the interspaces, using the ball vibratode and anteriorly apply the abdominal vibration and interruptions over the affected parts.

Mechanical vibration is contraindicated in pyosalpinx and pelvic abscess. Vibratory treatment of the vagina is indicated in relaxed walls and vaginismus. Enlarged prostate and prostatitis may be treated by local rectal vibration from three to five minutes, the rectal vibratode having a moderate amount of rigidity. In the treatment of hemorrhoids vibration lessens pelvic congestion and stimulates the return circulation. A prolonged rectal treatment is indicated.

Mechanical vibration in the treatment of pelvic conditions, alone, or with the use of light, electricity, hydrotherapy, or exercise as an adjunct, when applied with the proper care and technique, is a measure which from the results obtained appeals both to the layman and the profession, simple yet effective, easily applied, and not disagreeable. It is a most useful and valuable agent in the hands of the profession doing the physician's noblest work—the alleviation of human suffering.

Action of Drugs at Night.—Everything else being equal, remedies are more effective in the night than by day. This is owing to the fact that at night the processes of absorption are quickened and those of elimination abated. For the same reasons toxicity of drugs is greater at night.—*Medical Council.*

PHYSIOLOGICAL ACTION OF THE MOUNT CLEMENS MINERAL BATHS.

By RICHARD LEUSCHNER, M.D.,

MOUNT CLEMENS, MICHIGAN.

For a long time quite an uncertainty prevailed whether the action of mineral baths was based upon a direct transudation through the cuticle and its absorption into the system, or whether it was brought about solely by the external excitation incurred to the nerves of the skin. The holders of the latter view accepted the theory that the transmission of the stimulus extended from the peripheral nerves to the trophic nerves, or, rather, to those nerves supplying the muscles of the vascular walls would tend to regulate the circulation of the blood in the diseased tissue.

In a former article on the physiological action and effect of mineral baths, I conclusively proved the ingress of sulpho-iodo-bromo-salines through the skin and their resorption in the system by having isolated bromine and iodine from the urine of bathers, which findings should indicate that the composition of this water entering the organism, plus the external stimulus, would demonstrate a decided action upon metabolic changes.

Probably the curative virtue of some baths might depend alone upon the external stimulus of the cutaneous nerves; however, in both instances there still exists an obstacle to a full comprehension of the correct action of mineral water bathing, inasmuch as nothing has as yet been directly proven how the changes in the diseased tissues are brought about. For this very reason it is necessary to enter a little more fully into some of the causes that control the general processes of the body metabolism.

It has been universally assumed and accepted that the food products from the intestines reach the heart by passing through the lymph channels, especially the thoracic duct, the heart then distributing them through the blood-vessels to the different organs of the body. The correctness of this view has recently been attacked by Dr. Wachenfeld, a well-known authority at Bad Nauheim. In a brief article on "some observations concerning the mechanism of the circulatory system," he attempts to prove some facts contrary to the above accepted doctrine.

He points out among other things that at the present time very little is known concerning the actual metabolic changes in the cellular tissues, and claims that our knowledge over this matter ends in the intestinal tract. We have, he says, not fully grasped what takes place in those cellular walls, how the actual nutritive processes are carried on in the different organs, how the material for building cellular tissue is supplied, nor have we a correct conception of the elimination of body waste. These are physiological problems not satisfactorily solved. Dr. Wachenfeld then goes on to show that the submucous lymph vessels in the intestines are preferably the true lacteals carrying their material to the thoracic duct, that the outer intestinal lymph plexus supplies the walls of the intestines; he points out that these two sets of intestinal lymphatics are linked very closely together, and alludes conclusively to an important point that not all of the resorbed alimentation passes into the thoracic duct, but that a certain amount is absorbed directly from the intestinal canal into the body tissue.

We are here confronted with numerous questions and problems: What part does the chyle perform in the blood and what becomes of the lymph that

passes through the ductus dexter into the blood? Both liquids are at times entirely different. The nutriment that passes into the blood through the thoracic duct freshly resorbed from the intestines at the time when digestion is active, and that which enters through the right lymphatic duct into the vena subclavia dextra, must necessarily have found its way through body tissue.

Accordingly, then, what changes has the chyle undergone before it is given off from the blood into the tissue spaces? We assume, at least, that a part of the alimentation finds its way directly into the lymph currents, consequently the drainage system of those lymph channels plays a most important rôle in the process of the metabolism. Wachenfeld's clinical convictions on these points are most consistent with those that Wundt has laid down in his textbook on Physiology. Wundt declares that it is possible that the lymph during its slower movements through the interstitial canal system coming in a more immediate contact with the tissues than does the blood, serves as an important factor in the nutrition of these tissues. Principally does this rôle seem plausible where the lymph is devolved in the preparation of the glandular secretions, as approximately in most if not in all glands the parenchyma is surrounded by lymph spaces. Eventually then the liquids transuded from the blood enter the tissue spaces and only then through the thus separated lymph do the gland cells manufacture their secretions.

This important significance of the lymph in the nutrition and production of the secretions correspond with the fact that the lymph carries much larger quantities of decomposed material out of the tissues than the venous blood.

In reference to the action of Mt. Clemens mineral baths the following question now comes up for discussion and consideration: Are the ingredients contained in the water and, finding entrance into the system conveyed to the blood-vessels, acting in this wise upon the diseased tissues, or do they select the lymph channels to reach diseased tissues?

In the first instance the resorbed mineral substances, no matter how manifestly small the amount of their transmission into the blood, and even if they could not be detected analytically therein, would necessarily create a chemical stimulus to the blood influencing the action of the heart and the consequent pressure in the vascular walls. In order to determine this I undertook to test the blood pressure before and after the baths upon some twenty patients. The examinations were made one hour before and one hour after the baths.

Before.	*After.*	*Before.*	*After.*
85 mm.	85 mm.	100 mm.	115 mm.
80 "	95 "	100 "	85 "
95 "	80 "	85 "	100 "
115 "	115 "	115 "	115 "
110 "	110 "	95 "	95 "
95 "	105 "	95 "	85 "
105 "	105 "	120 "	120 "
95 "	80 "	95 "	95 "
95 "	95 "	90 "	95 "
100 "	100 "	85 "	85 "

Accordingly a considerable increase of the blood pressure was not established. In four instances there even was a falling of the blood pressure, which I am inclined to attribute to increased distribution of the blood in the cutaneous vessels. In the majority of the cases the examination showed no material change before or after bathing; in five cases, however, a regular increase of the blood pressure was observed after the bath, although the same was only moderately larger, never reaching over 15 mm. more than before the bath.

It would seem to me that a stimulus of the muscular structure of the heart and blood-vessels does not occur as a result of the resorption of our mineral water, and we must consequently assume that the same is brought about to a large extent through its entrance through the skin into the lymph channels and not into the blood current. As an objection to this contention could be raised the point that iodine and bromine in minute amounts were isolated from the urine of bathers and that the mineral ingredients must necessarily, therefore, have passed through the blood-vessels.

The late physiologist Heidenheim promulgated the theory that the fluids of the urine are separated through the capillaries of the glomeruli and the salts through the walls of the uriniferous tubules. Liebig showed by an experiment that there might possibly be some doubt regarding this. He proved that, by the drinking of a glass of water containing a smaller quantity of salts than the blood on an empty stomach and repeating the same every ten minutes a decided diuretic action is manifest. With the ingestion of the second glass a quantity of urine is secreted which approximately corresponds with the weight or volume of the first glass drunk; and, if in this manner twenty glasses are taken, the last urine is colorless and its percentage of salts will be about the same as that of the first glass of water taken. It is impossible that in so short a time so large a quantity of water could pass through the blood current without causing a large dissolution of the ingredients of the blood. We must therefore conclude that the excretion of urine which was naturally quite large is substantially carried on through the very markedly developed lymph vessels of the kidneys which receive their material from the whole lymphatic system of the body.

How is the action and effect of the resorbed ingredients of the sulpho-iodo-bromo-salines into the organism explained? The solution can only be found in the presumption of the existence on an increased lymph current. Only the increased mechanical force and larger amount of lymph fluid can dislodge and wash out the diseased cells from the diseased tissues. The mineral water finding ingress into the system during the bath must necessarily and beyond all doubt act by stimulating the lymph movement.

Heidenheim accepted the belief that the increase in lymph fluid manifested itself in two ways, either in the absorption of an augmented amount of liquid from the blood into the lymph channels or through the transfer of water from the tissue spaces. Now, this increase of lymph-fluid can be brought about by different substances circulating in the lymph-channels and Heidenheim characterized these ingredients as "lymphagogues." These lymphagogues stimulate the nerve tissues, and in this manner all glandular and analogous structures of the body are forced to an augmentation of secretion.

That the excitation to the nerve tissues will actually produce an increased function of the glandular secretions was proved when Heidenheim some time ago, by stimulating the chorda tympani nerve, induced an almost immediate increase in the flow of saliva.

Other investigators, including O. Nasp, Hirschmann, *et al.*, have found that the grade of irritation of the nerves is more or less controlled by the strength of saline solution acting upon the same.

THE USE OF BACTERIAL VACCINES.

By HARRY BRITENSTOOL, M.D.

NEW YORK.

THE degree of interest shown by physicians throughout the world in the biological methods of the treatment of diseases of microbic origin has placed the opsonic theory in the center of the stage. I am not in a position to discuss the possible value of this theory, nor to aid in the elaboration of any new ideas on the subject. As a general practitioner, unacquainted with the more minute pathological technique, I rather incline to the belief that the determination of the opsonic index of a specific case will be of little value to the average practitioner. Nevertheless, the ultrascientific investigator will doubtless render us a great service by estimating the correct dosage, the best methods and time of administration, and the danger limits in the use of bacterial vaccines. The determination of the exact relation existing between vaccines prepared directly from a specific case and the so-called "stock" vaccines, rests not only with the pathologist, but also with the clinician.

As the fundamental basis of medicine is empiricism, I have taken advantage of our limited knowledge of bacterial vaccines and have used "stock" vaccines of mixed staphylococci with splendid success. I have not used them in a sufficient number of cases to demonstrate fully their efficacy, but my results so far have been so positive that I am submitting three of my cases to augment whatever experience others may have had with such vaccines.

CASE I.—S. C., woman, aged 23, weight 124, blonde. Over a year previous to the commencement of treatment by me, the patient developed an acne on the face. This had been treated by a specialist for nine months with only fair results. Seven months after the first development of the acne, a furuncle made its appearance on her thigh. This was treated locally and sulphur, cream of tartar, and calcium sulphide were administered per os. Under this treatment the furuncle and consequent glandular enlargement disappeared. Two months later, three abscesses, located on the perineum and buttocks, made their appearance. For a period of three weeks, these were treated by a woman physician. When another made its appearance, the patient, who was one of my regular clientèle, came to me for treatment. Owing to her peculiar disposition, I was unable to make an examination. After gaining the consent of the patient, at the same time explaining that the treatment was experimental, I injected one tube of vaccine containing 400,000,000 saphylococci of the aureus, albus, and citreus varieties. The injection was given in the lumbar region and, with the exception of some local tenderness and redness, which soon disappeared, no ill effects followed the administration. At intervals of five days two other injections were given, with the result that the abscess that was forming resolved without any local treatment and her face as well as the other infected parts became normal. Her complexion is now perfect, and the patient is delighted with the results. There is at this time no semblance of a return of the infection.

CASE II.—F. A., woman, aged 21, athletic build, complexion dark, employed as a confidential clerk, came to me complaining of a number of pustules and abscesses on the buttocks, perineum, and pubes. The pus on examination contained only staphylococci, but no culture was made to determine the variety. My treatment for the first two months consisted, locally, of the opening and cleansing of the abscesses with hydrogen peroxide and internally calcium sulphide, small doses of mercuric iodide, etc. I also had her dispense with the use of undergarments that were liable to increase the local irritation. As she was hypersensitive to the local treatment, I explained the experimental nature of the bacterial vaccine and advised their use, to which she agreed. In this case I administered two injections of the (combined) staphylococcus vaccine with an interval of six days between the injections, the selected site being the upper part of each thigh. Following each injection, there was a swelling with some redness and tenderness, but the day following each injection, the patient fulfilled her usual business duties without inconvenience. Improvement of the condition was noted as a result of the first inoculation, the second being sufficient to eradicate completely the infection. It is now over eight weeks since this treatment was employed and there is still no semblance of a return.

CASE III.—L. M., man, aged 35, height 5 feet 11 inches, weight 169, a stock-broker who had been suffering for some time with furuncles on different parts of his body. These had been regularly treated by his local physician with the conventional remedies. As soon as one would resolve another would make its appearance on a new site. Upon examination, the staphylococci were again demonstrated, but no cultures were made. I did not determine the variety, and therefore a mixed vaccine was again employed. In this case the first injection of 400,000,000 bacteria caused a complete cure of the condition, and the treatment was so satisfactory to the patient that he stated that, should he ever again become infected, it would be the only treatment he would accept.

These results, though not conclusive, warrant a close study of this interesting method of combating disease.

783 LEXINGTON AVENUE.

Deafness of the New Born.—W. Koellreutter has recently made a series of tests on new-born children and finds that the deafness often observed then is referable to a disturbance of the sound conducting apparatus of the ear. His material consisted of twenty children. They were all examined in a sleeping or a half-sleeping condition. The source of tone was the Bezold-Edelmann tone series, and the examinations were only made by air conduction. To compare his results with those of Moldenhauer, he also used the musical toy, the cricri. Of the tone series he made use of the following forks—subcontra C, c^2 and c^3, and Galton's whistle c^6. The tuning-forks were set in vibration so that no impression could be conveyed to the child either optically or by a draught. The Galton whistle was approached to the ear without causing any current of air. The results were observed by three persons who were witnesses to the examinations. The room for examination was a quiet room. The children were repeatedly examined for several days and at different times of the day. Koellreutter finds that: (1) The cricri produces in all the children a distinct reaction at all times, even a few hours after birth. (2) The tones c^6 of the Galton whistle produced a distinct reaction in: (*a*) all children within the first 24 hours after birth. (*b*) 74 per cent. of all the children between 2 and 4 days old. (3) The tuning-forks subcontra C, c^2 and c^3 never produced any reaction. He therefore finds a good reaction to high tones from birth, while deep and middle tones in the first days apparently were not perceived at all. He has been able to show that all new-born children reach to high tone c^6 on the first day of life while the deep tones are not perceived. It seems therefore there is no reason to doubt the power of irritation which the auditory nerve possesses in the early age of children. This irritability in the light of present knowledge is shown by this reaction to the high tone c^6 while the insignificant reaction to the other deep tones points to a disturbance of the sound-perceiving apparatus for which there is a well-known anatomic foundation.—*Archives of Otology.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, August 8, 1908.

HEATSTROKE, HEATCRAMPS, AND LIGHT PROSTRATION.

A VALUABLE contribution to the etiology of sunstroke and heatstroke was published in the January number of the *Journal of the Royal Army Medical Corps*, by Major Leonard Rogers, I.M.S., who makes a careful distinction between the syncopal cases, which he calls true sunstroke, and the more fatal heatstroke, or thermic fever, characterized by fever and coma. He combats the microbic theory of Sambon and Manson, who asserted that heatstroke prevailed capriciously as far as atmospheric temperature is concerned, and that it was found only in low countries, never above 600 feet elevation. He shows by elaborate statistics that the cases occur everywhere in India and are strictly dependent upon high atmospheric temperature as to both the hottest months of the year and hottest hours of the day, and that high humidity increases the effect of the heat. Humidity merely prevents evaporation of perspiration and loss of body heat, for cases are practically unknown in our arid West, where the dryness of the air causes enormous evaporation. The symptoms are due to the fever and are cured by a reduction of the body temperature. There is no relation to the direct rays of the sun except their heating effect, and cases may occur from exposure to heat in shaded rooms. "Sunstroke," or what we call "heat prostration," he says, always follows sun exposure, as in marching troops, and is very amenable to treatment. This corresponds to many previous observations, which ascribe these syncopal cases to the effects of excessive light, and it should be proper to designate them as "light prostrations" if they never occur except after exposure to excessive light.

Another group of cases due to heat was described by Surgeon M. S. Elliott, of the U. S. Navy, in *The Military Surgeon* for March, 1908, though the cause of the symptoms is not stated. His cases occurred among those exposed to the heat of the firerooms of ships, where the air temperature is often as high as 140° F. The main symptoms are subnormal temperature, muscular cramps, profuse perspiration, and collapse. After copious high enemata of hot physiological salt solution, improvement was almost instantaneous, so the cause of the condition is probably the high specific gravity of the blood from the loss of body fluids in the excessive perspiration. The condition is practically the same as that found in cholera, when the fluids drain off by the bowel. These heat cases have been repeatedly described in many parts of the world, and suggestions have been made to use saline solution intravenously. It is also an old tropical observation that if ample water is not drunk during excessive perspiration the urine may be so concentrated as to cause acute inflammation of kidneys, bladder, and urethra, lighting up old gonorrheas, and there may be rheumatic and obscure nervous symptoms, probably from defective elimination of waste products.

Elliott says the cases are far more numerous among negroes, who, contrary to the general impression, do not stand a high heat as well as white men. It has also been stated that negroes suffer unduly from true "heatstroke." The black skin is apparently evolved to exclude the excessive light of the tropics, where the heat is never so intense that there is special need of other protection than by the evaporation of perspiration. Consequently, they are at a disadvantage when exposed to very high temperatures, such as they never encounter in their native state, as dark surfaces absorb heat better than light ones.

There is ground for the belief that white men, upon exposure to the sun's rays, suffer more than negroes from the syncopal forms, and Rogers may be right in calling these cases true "sunstroke," though "light prostration" might be a better term, as "sunstroke" is generally used for "heatstroke" or "thermic fever." There should be a better differentiation of cases and new descriptive terms invented, for some of the cases are neither "heatstroke" nor "light exhaustion," but purely results of the loss of body fluids, and there may be all conceivable mixtures of these cases.

It would be of value to determine whether our syncopal forms are more common in the lightest months and lightest parts of the day, and whether blonds suffer more than brunets, and the latter more than negroes. Protective measures could then be devised. Recent observations have established the fact that the loss of vitality of soldiers long resident in India is due to the actinic, and not the thermic, rays, and it is being suggested that they be housed in mid-day, and if compelled to be outdoors that the clothing be opaque, and the hats large and of wide brim, like the native's headcovering. It now seems that in our summers an umbrella may be more necessary on sunny days than on rainy days.

PUBLIC MEDICINE AND ITS RELATION TO SOCIETY.

THE rôle of the physician has changed greatly during the past few years. At a time not long ago, his sole recognized office was to treat and cure, or try to cure, disease. Whatever may have been the results of his efforts in this direction, and statistics seem to show that they were not unsatisfactory, at least so far as his own pocket was concerned they were more favorable to him than they are now under existing conditions. Prevention of disease, rather than treatment, is the object now aimed at, and the physician is coming to be regarded more as a worker for the community at large than for the individual. In times that are past, or passing, the medical man's only place was in the sick room and in the hospital, where, naturally, he was all-powerful.

Now he is not only the dictator in the sickroom and in the hospital, but his presence has been demanded in the school, the workshop, the factory, and the mine. Formerly, the function of the physician was to attend to the sufferings of the sick, but at the present time his scope of work has been greatly amplified, and his labors have been extended to the care of those in apparent health, in order to ensure that the conditions under which they live are such as not to endanger their health and vigor. In fact, what with notification, isolation, medical inspection in schools, the physician is really oftentimes more of an official than a medical guide. The question is, has this evolution and development worked for the public good.

Dr. Alexander James, speaking in Edinburgh, on July 1, on this subject, concluded that much of the public health work carried on during the past twenty or thirty years had not been attended with any strikingly successful results. It had been recognized that the assumption by communities of individual responsibilities had many disadvantages. Apart from the fact that it struck a blow at family life, it had the effect of lessening that feeling of responsibility in the individual that begot self-dependence and frugality. On the other hand, it was argued that measures which were for the physical and moral welfare of the community at large would more than counterbalance any disadvantage to the individual. Dr. James, however, endeavored to show that this interference of the community with the liberties and responsibilities of the individual which public medicine had brought into existence within the last quarter of a century had not been doing all the good which was claimed for it. He demonstrated by means of tables and figures that the mortality from phthisis between the years 1860 and 1905 in Edinburgh, Dundee, and Aberdeen had decreased, but this result was due to progressive voluntary efforts of individuals. With regard to typhoid fever in the same period, and in the same cities, the enforcement of legislative enactments did not appear to have improved matters. As regards measles, statistics showed that since notification and isolation the mortality had increased rather than diminished. As regards diphtheria, figures showed improvement in all the towns, but not especially after compulsory isolation, and the improvement was not more marked than was seen in phthisis without isolation. Dr. James' object was to show that the strict isolation measures of the past fifteen or twenty years in Great Britain stood condemned on their own showing, and that distinct modification was now required. He was strongly of the opinion that the functions which physicians in many cases had been performing were not what were in their own interests or in the interests of the community. Of course, the movement in the direction of prevention of disease rather than treatment, has taken a firm hold in all countries, and is likely to progress. Furthermore, a large number of physicians will not agree with the conclusions of Dr. James. These contain a basis of truth, and it may be that the new departure has not by any means all the merits which is claimed for it. At any rate, it is refreshing and instructive to hear the other side of the question. It leads to thought on the subject, and if, as we believe, public health measures, including notification of contagious diseases, are beneficial to the community, the discussion aroused by opposition such as that of Dr. James, will speedily demonstrate the fact.

THE QUESTION OF THE SPECIFICITY OF THE WASSERMANN REACTION.

The many observers who have given the Wassermann reaction a trial have found it present in a large percentage of syphilitic patients. Wassermann, Neisser, and others hold, indeed, that it is a specific reaction, but Weil and Braun, on the other hand, have repeatedly opposed this claim, and in the *Wiener klinische Wochenschrift* of June 25 they adduce further evidence in substantiation of their belief. They found a positive reaction in four out of twelve cases of croupous pneumonia, in three out of twenty of typhoid fever, in two out of twenty-one patients with tuberculosis, in one out of four diabetics, and in four out of fourteen patients with malignant growths. In all of these patients syphilis was ruled out. Those patients in whom the reaction was negative had light forms of the diseases mentioned, while extensive pathological changes were found in those in whom the reaction was positive. This led Weil and Braun to believe that the blood serum reaction was due to the products of cell disintegration circulating in the blood. They employed the same technique as Wassermann and his followers, and made several tests in each case. They also obtained a positive reaction in syphilitic and paretic patients when using extracts from normal organs instead of extracts of syphilitic organs.

However, even though these observers appear to have shown that the reaction is not specific for syphilis, it cannot be denied that it has some practical value. They themselves admit it is of value when diabetes, tuberculosis, malignant growths, and a recent pneumonia or typhoid fever can be excluded. Furthermore, they tried the reaction with the blood only, and not the cerebrospinal fluid of nonsyphilitic patients, so that a positive reaction with spinal fluid may still be regarded as pointing to a diagnosis of syphilis, at least until positive reactions have been obtained with the spinal fluid of nonsyphilitic individuals.

Reversal of the Circulation in the Prevention of Angiosclerotic Gangrene.

The so-called "spontaneous" gangrene of the older writers has been properly traced to the effect of localized degenerative changes in the blood vessels of the extremities, and the views in reference to the ultimate etiology of the affection as well as to the proper treatment of it have undergone corresponding modification. Alcohol has been looked upon by many as the most important factor in the production of such sclerotic changes in the arteries, but the observations of physicians working among the Mohammedan races do not lend support to this view; thus, Dr. Wieting notes the relative frequency of the disease among the total abstainers in the Oriental countries, over one hundred cases having come to his notice within six years of routine hospital practice in Constantinople (*Deutsche medizin-*

ische Wochenschrift, July 9, 1908). In his opinion, alcohol is but one of the many toxic substances that may lead to the disease in question, tobacco and the toxins of the infectious diseases being the probable etiological factors in his cases. Attacking, as it often does, persons of middle age, or even in early adult life, angiosclerotic gangrene must be looked upon as one of the most serious affections; warm baths, artificial hyperemia, continuous elevated position of the affected limb, are only slightly useful in the treatment of it, and sooner or later an amputation must be performed to save the patient from a worse fate than the loss of a limb. The author properly warns against the application of an Esmarch bandage in the determination of the site for amputation as well as during the operation itself. Careful attention to the differences in the warmth of the surface is quite sufficient for determining the part of the limb that must be sacrificed. In connection with operative treatment of the disease, Wieting reports an interesting case, in which partial reversal of the circulation in a limb was effected, the result quite approaching the success obtained by Carrel and Guthrie in experimental work upon dogs (*Annals of Surgery,* 1906). Dr. Wieting's patient had already lost one leg by amputation because of gangrene, and readily agreed to the tentative performance of an arteriovenous anastomosis, which promised to save his other leg, that was beginning to be affected. The implantation of the femoral artery into the corresponding vein was followed by gradual remission of all threatening symptoms, and complete recovery of the limb resulted. It is probable that this is the first case in which such an operation, that has been quite effective in the experimental work upon animals in the presence of healthy tissues, has succeeded in an advanced pathological condition affecting a human being. Wieting, however, very properly speaks of the result as, probably, only a temporary success. The rapid advance of gangrene was certainly stopped in his patient: that its progress was put an end to completely is hardly to be assumed, in view of the present conception of the etiological factors of the disease, to which we have referred in the beginning of this notice, and which no change in the direction of the blood stream would be likely to affect permanently.

Diphtheria Antitoxin in the Berlin Epidemic.

The use of diphtheria antitoxin has become so general that no defense of it is necessary at the present time. The few individuals who still claim that the specific treatment of this disease has not lowered the mortality, the apparent decrease in the death ratio being due to the many mild cases that are now diagnosed and reported, are probably beyond conviction by any arguments that may be adduced. The nature of the disease, however, is such that the use of antitoxin cannot prevent the appearance of epidemics; an attack of diphtheria does not confer immunity for any great length of time, the artificial immunity afforded by antitoxin is also very short in duration, and the chances of infection are almost always present, especially in children of the school age. These reasons explain the recent reappearance of diphtheria in epidemic form in Berlin in the year 1907, during which 3,447 cases occurred in the city, 520 of them being observed by Baginsky in the Children's Hospital (*Berliner klinische Wochenschrift,* July 6, 1908). But while the epidemic could not be prevented, the mortality as compared with the earlier figures gives fair evidence that the danger from the disease has gradually diminished even since the introduction of specific treatment, most of the profession having been educated to the value of early and sufficient doses of the antitoxin. Of Baginsky's cases 11.9 per cent. died; the mortality in the early days of antoxin was 15.6 per cent., and in the pre-antitoxin days it reached from 30 to 50 per cent. of the cases. The epidemic under consideration, too, was quite severe in character, the larynx being involved in 110 patients. The deaths occurred in patients in whom the antitoxic serum was used late in the disease, in many cases the dosage being much below the usual amounts recommended by the best authorities; several other deaths could be traced to complications, on which the specific treatment could have no effect in the very nature of things, coincident infection with scarlet fever having occurred in a few cases, while in others the fatal outcome resulted from the accidents of tracheotomies. The study of this epidemic leads Baginsky to reiterate the great advantage of early use of the antitoxin, in amounts ranging from 1,500 to 5,000 units, the day of the disease, the severity and site of the lesions, the age of the child and its physical development being the factors in computing the size of the dose to be used in each individual patient. In a recent discussion, Guradzi, in answer to those sceptical of the value of specific treatment in diphtheria, said that the mortality, with the further development of serum therapy, will drop to such low figures that the present minimum will appear appalling, and Baginsky urges the profession to show greater confidence in the value of antitoxin by using a sufficient amount of the remedy as early in the disease as possible, and thus hasten the results anticipated by Guradzi.

The Tuberculo-opsonic Index in Pregnancy.

In the last decade much has been written concerning the morphological and chemical changes in the blood during pregnancy, but few investigations have been made regarding the presence of opsonins at this time. In the *Wiener klinische Wochenschrift* of April 2, 1908, K. Koessler and W. Neumann discuss the effect of pregnancy on the opsonins normally present in the blood. To ascertain this they compared the opsonic indices for the tubercle bacillus in a number of healthy pregnant and nonpregnant women. They considered any index normal which ranged between eight-tenths and one and two-tenths. Among sixty-five clinically nontuberculous pregnant women only forty-eight per cent. showed a normal tuberculo-opsonic index during the last month of pregnancy; among twenty-three nontuberculous women in the puerperium the percentage of normal indices was also forty-eight. Among healthy nonpregnant women other observers have estimated the percentage of normal tuberculo-opsonic indices to be eighty-seven or higher. From which Koessler and Neumann conclude that the normal opsonic content of the blood becomes diminished in many women during pregnancy and the puerperium. It is true that they have shown this in regard to tuberculosis, but similar tests would have to be made with other bacilli before we should be justified in stating that the blood shows a lowered resistance for all diseases during pregnancy. Nevertheless the findings in regard to the tubercle bacillus are amply substantiated by the clinical experience that most women do not withstand tuberculosis as well during pregnancy and the puerperium as they do at other times.

News of the Week.

Medical Schools Merge.—Louisville, Ky., is to have one large medical school in the place of the five existing a year ago. Articles of agreement have been signed by the trustees of the University of Louisville, the Louisville Medical College, and the Kentucky School of Medicine. Last year the Hospital Medical College was merged with the Louisville Medical College, and the Kentucky University of Louisville. The Kentucky State University has been asked to make the merged school the medical department of the University. The faculty will number between seventy-five and a hundred, and the number of students is estimated at about 700. The buildings which have heretofore been used by the separate schools will be available for classrooms and laboratories, and a movement is on foot to erect a new City Hospital, in which clinical instruction may be given.

Civil Service Examinations.—An examination will be held by the United States Civil Service Commission on September 2 and 3, 1908, for the purposes of securing eligibles from which to fill a vacancy in the position of first assistant surgeon (male) in the Freedmen's Hospital. Application should be made at once to the United States Civil Service Commission at Washington. The Freedmen's Hospital is an institution for the treatment of colored patients, and it is the practice of the Department to appoint only colored persons to positions therein. The salary is $1,500 per year.

On August 26, 1908, the same Commission will hold an examination for the purpose of filling the position of clinical director in the Government Hospital for the Insane, at a salary of $2,000 per annum, with maintenance. Applicants must be graduates of a medical college, have had at least ten years' experience in institutions for the care of the insane, and be not over thirty-five years of age. The appointee will have general supervision of all the medical work of the hospital. Application should be made to the United States Civil Service Commission at Washington.

The Opium Evil.—Since 1878 the importation of smoking opium into the United States has increased more than 250 per cent. according to facts collected by the American commissioners appointed to attend the international congress to consider the question which meets at Shanghai next year. During 1907, 157,000 pounds were imported, about 75 per cent. of which is used in the manufacture of morphine. Reports indicate that in the United States the use of opium as a habit has grown to an alarming extent and that this growth is not among the Chinese residents, but is among the whites, not so much in the slums as among the professional classes. Chinese doctors have devised a cure and are impressing on their countrymen the destructive influences of the use of the drug, and among the Chinese here strong efforts are being made to abolish the habit. On the other hand, it is estimated that there are 5,000 white persons who are smokers of opium in New York City. The "strenuous life" is again brought forward as a reason, or excuse.

New York's Death Rate.—For the week ending July 25, the death rate was 18.50 per 1,000, the total number of deaths being 1,568. Last year during the corresponding week the rate was 22.05, and the total number of deaths 1,811. In 1907, the number of deaths of children under five reported during the week reached 949; this year the total was 739. For the week ending August 1 the death rate was 16.63 per 1,000, against 21.98 for the corresponding week in 1907. The total number of deaths was 1,410 this year, compared with 1,804 in the corresponding week last year.

Immigration Cut in Half.—During the twelve months ending June 30, 1908, 585,970 immigrants came into the Port of New York, but little more than one-half the number entering during the preceding twelve months.

Death Rate in London.—The reduction in the death rate in London, which has recently been marked, has been ascribed to the decrease in horse traffic on one hand, and to the increase in motor traffic on the other. The anonymous author of this attempt at an explanation states that the fumes from motorcars and omnibuses are the finest possible disinfectant, clearing the air of germs and impurities. The vapors from the cars are in reality health tonics and bracers, instead of the nuisance we have generally thought them. And yet the park commissioner of this city has barred the smells from Central Park, when perhaps those are precisely what the rhododendrons are pining for.

Contagious Diseases in Chicago.—The small number of deaths from contagious diseases in Chicago during the past week has been noticeable. There were but six from diphtheria, two from scarlet fever, two from measles, and two from whooping cough.

Charitable Gifts.—The Association for Improving the Condition of the Poor has received from Mr. G. H. F. Schrader a gift of $500,000, part of which is to be used for the construction of a new building for "Caroline Rest" a home at Hartsdale, N. Y., for the benefit of mothers convalescing from childbirth. The gift also provides for the endowment of the home.

Hospital for Tuberculous Patients.—The Board of Supervisors of Rensselaer County, N. Y., have appropriated $25,000 for the erection of a hospital for advanced cases of tuberculosis, which will accommodate sixty-five patients. Investigation had already showed that with a large number of cases of this disease in Troy, especially among the poorer classes, the county almshouse was the only institution where such cases were admitted, and that accommodations there were very unsatisfactory. The new hospital will therefore fill a great need, and be of immense value in the control of the disease.

Hospital Burned.—The City Hospital of Lock Haven, Penn., was destroyed by fire on July 28, after the thirty patients in the institution had been safely removed. The loss is estimated at $45,000.

St. Bernard's Hospital, Chicago.—Dr. Thomas J. Sullivan has been made chief of staff, and Dr. Charles P. Caldwell, head of the dispensary, of this hospital.

The American Hospital Association.—Because the large number of meetings and conventions arranged for the latter part of September in Toronto has made it impossible to secure adequate hotel accommodations at the previously announced time, the date of the meeting of the American Hospital Association has been changed to September 29 and 30, and October 1 and 2. The meeting will be held at the King Edward Hotel, Toronto.

Cholera in Russia.—An outbreak of Asiatic cholera has been reported in three provinces of Russia. Two deaths have occurred at Astrakhan City. In Tsaritsyn eleven deaths have been reported out of twelve cases. The disease is said to be of a most virulent type.

Mrs. Esther Davis, living at the Home of the Daughters of Jacob, New York, on July 29 celebrated her 114th birthday. Mrs. Davis was born in Russia and came to this country when 89 years old. She is still in good health.

Yellow Fever in Cuba.—Three Spaniards have been reported ill of yellow fever at Cobre, Santiago. One death occurred on July 29.

The Rutland County (Vt.) Medical Society held its annual meeting on July 14. The election of officers for the ensuing year resulted as follows: *President,* Dr. W. W. Townsend; *Vice-President,* Dr. H. L. Martyn of Cuttingsville; *Secretary,* Dr. William Stickney: *Treasurer,* Dr. H. R. Ryan.

Obituary Notes.—Dr. Paul S. Redfield of Providence, R. I., died at his home on July 19, aged 70 years. Dr. Redfield was graduated from the medical department of New York University in 1866. Owing to failing health he had practiced but little of late years.

Dr. Andrew O'Malley of San Antonio, Texas, died on July 20, after several months' illness. Dr. O'Malley was graduated from the College of Physicians and Surgeons, New York, in 1890, and served as interne at the Roosevelt Hospital. He was for a time connected with the New York Polyclinic and had written largely on medical subjects.

Dr. Claibourne Watkins of Little Rock, Arkansas, died at his home on July 20, after a long illness, aged 64 years. Dr. Watkins, after serving with distinction in the Confederate Army, was graduated from the Jefferson Medical College at Philadelphia in 1868. He was one of the founders of the medical department of the University of Arkansas, and for a long time served on the faculty of this institution. At the time of his death he was a professor emeritus.

Dr. William Henry Snyder of Brooklyn, N. Y., died at the Seney Hospital on July 30, of appendicitis, at the age of 24 years. He was graduated from the Long Island College Hospital in 1903, but for the last two years had engaged in business.

Dr. Edward Vincent Brown of North Tarrytown, N. Y., died on July 25, in Portland, Oregon, at the age of 71 years. Dr. Brown was a graduate of New York University medical school in 1863, a member of the American Institute of Homeopathy, and a visiting physician on the staff of the Tarrytown Hospital.

Dr. Alexander Hamilton Laidlaw of New York died on July 29, at his home, aged 80 years. He was graduated from the Hahnemann Medical College in Philadelphia in 1861, and had not practiced since 1905. He was the author of several works and had been always greatly interested in educational subjects.

Dr. Horace Y. Evans of Philadelphia died at Breakwater, Me., on July 23, at the age of 74 years. He was graduated from Princeton University in 1855, receiving the bachelor's and master's degrees; and from the medical department of the University of Pennsylvania in 1858. Subsequently, he prosecuted post-graduate studies abroad. During the civil war he served as a surgeon in the United States Army, entering the service with the City Troop in 1860.

Dr. Franklin J. Evans died at Chester, Pa., on July 29, at the age of 45 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1884. He was President of the Delaware County Medical Association, Physician to the Baltimore and Ohio Railroad Company, and he was a member of many fraternal organizations.

LETTERS TO A NEUROLOGIST.

To which is appended brief replies purporting to set forth concisely the nature of the ailments therein described, with remarks on their appropriate treatment.

X. From a Lady Who Seeks the Deliverance of a Sister Who Is Jealous.

My Dear Doctor:—I wish to make an appointment with you for my sister, Mrs. ———. She will be here next Monday to stay a fortnight. I am greatly concerned about her, and as she is seeking your counsel at my urgent solicitation, I feel at liberty to tell you something of the conditions, as far as I know them, under which she is struggling. I am convinced that she is not only sick in body but mentally ill as well, otherwise her weakness, backache, apathy, and depression cannot be explained.

My sister and I were left orphans at an early age. My father died when I was seven and my sister but an infant. My mother lived on, a heartbroken invalid for ten years. When she died, I was seventeen; my sister, not quite eleven, was a delicate creature, having, I am told, suffered much from digestive trouble in her infancy, and been threatened with rickets.

From a child she would devote herself passionately to one person in whom she lived and breathed. She could be, apparently, in the seventh heaven of delight, when a cold word or an indifferent look from the beloved one would plunge her instantly into the depths of gloom. When we were left alone in the world she became deeply attached to me, and had she not fallen in love I should have considered it my duty to refrain from assuming more intimate ties and to guard and protect her always.

At twenty, however, she fell violently in love with a young man a few years her senior, whose family we had known always. Her engagement was a short one. She was married and nine months later her first child was born. Everything was apparently most felicitous in spite of the fact that she did not escape those hours of disappointment and disillusionment which fall to the lot of every young bride. It was at this time that I felt at liberty, my sister being settled, to seek my own happiness. I married an old friend, a German officer, and have lived in Germany for the last sixteen years. I have a large and engrossing family, and although I have kept in touch with my sister as much as possible, I haven't been under the same roof with her for any length of time, until my present visit, which is now terminating.

When my sister met me at the station her appearance gave me a shock. She looked almost transparent and her eyes had a strained, excited expression, which I had noticed in the past only at times of extreme exaltation. She seemed delighted to be with me, but instantly became reserved when I asked if all were well with her. Her husband, she said, with a shrug of the shoulders, was away from home amusing himself. Her boys, respectively 13 and 15, were at boarding school. She was alone. I did not notice during the first twenty-four hours that she was much changed, for we recalled the past and lived over in imagination many happy days long gone by. As time went on, however, my attention was attracted to a peculiar expression which seemed to come over her face at short intervals without apparent cause. Her interests in whatever subject we were discussing seemed suddenly to fade away—her face would get pale, her features immobile and her eyes fixed. Her thoughts were either far away

or her mind's door was closed. There was an impenetrable barrier of some kind between us. I perceived that my sister was not happy, that she had something on her mind, and that her natural reserve and sensitiveness led her to hide it from my searching eyes,—she seemed to be on guard.

It was two weeks or more before I could induce Mary to speak of herself and then she would let down the barriers only a few moments at a time. She would be on the eve of a confidence when she would suddenly become distant in manner and absolutely impenetrable. By degrees, however, I have learned the true state of affairs. The illness of one of my children calls me home and I am sailing in three days. I am in the throes of a divided duty and feel the greatest concern at leaving my sister, but I am convinced that under the circumstances the best thing I can do is to entrust her to your care, for I feel sure that you will know how to win her confidence.

But let me tell you what I know. I will try to piece together the bits I have gathered from her from time to time. She is, as I have said, morbidly sensitive and has an intense craving for approbation, and although a devoted and self-sacrificing mother, her instincts are more uxorial than maternal. She has sent her boys away from home for two reasons—the first, that she is not strong enough to be both wife and mother, and the second, she sees or imagines she sees, a growing antagonism between her husband and her eldest son, but more of this later. The husband came home a week after my arrival, and I took it upon myself to observe him closely. Years have but intensified his peculiarities. He has an iron constitution, a clever but uncultivated mind, inexhaustible spirits and a most exacting nature. He is easily bored and will take any means to escape boredom. He has no religious convictions—to him this world is all we have and he looks upon the man who does not grasp every pleasure that lies in his way and rush up every avenue that promises pleasurable sensations as an unmitigated fool. He is a law unto himself and recognizes no boundaries but his own limitations. My sister confesses to me that at different times her jealousy has driven her to thoughts of suicide, and there are indefinite rumors that at one time she acted irrationally for a few days. During their entire life together, beginning eighteen months after their marriage, her husband has had a succession of affairs—probably harmless in one sense, for they have been with women in his own class, often with his wife's intimate friends, and these women have lost neither position nor reputation. His intense vitality makes him irresistible to some women. For the time being, he lives only for the object of his admiration, whom he surrounds with every outward evidence of his approval whenever opportunity offers. In the ballroom, or in the country, his wife has purposely placed herself in a position to overhear what he may be saying to the woman whom he admires, and she has heard caressing compliments in the delightful, magnetic tones which won her own heart directed toward some one else.

For dreary days and sleepless nights she would eat her poor heart out—and then he would return to her. So far he has apparently never failed to return. Then would begin a struggle of another kind. She would try, in spite of her delicacy, to fulfill all his requirements—take long walks, exhausting rides, enter with apparent interest and enthusiasm into all his schemes. At these times he would devote himself to her. It almost seemed as if he would devour her soul and body. Then reaction would set in—he would seek alluring fields and pastimes new, go away from home alone and leave the poor little bruised being a prey to all the forebodings that a sick body and jealous mind could fabricate. At times I fear she must have been beside herself, but he always returned in time to restore her in part, and her broken condition seemed to appeal to a side, which, if you will believe me, is not his better side. It seems to me that he takes a certain satisfaction in seeing what devastation he has accomplished. My brother-in-law is now away on a shooting trip and I feel that my sister is in no condition to be left alone. I am also convinced that she needs medical advice and care.

She has been receiving treatment from a physician in ————————, who thinks she has some spinal trouble, a weakness of the spine. At times she complains of a great deal of pain in the back of the head and neck, and of fatigue, which apparently is not the result of exertion. At other times these complaints disappear suddenly and she will seem quite well. I do not know that I make my meaning quite clear to you, but there are periods when she seems quite normal; yet within a few days, nothing having apparently intervened meanwhile, she will go to pieces, become terribly depressed, apathetic and uncommunicative. One would think she was becoming a prey to melancholia.

One time the doctor gave her a rest cure, another time he burned her back, and lately he has been talking about sending her to a sanatorium. I haven't had much conversation with him about her, but I am convinced that in his interpretation of her condition he does not take into consideration the fundamental part that the mental or emotional element plays in her case.

I have observed her very closely during the past two months, and the result of my observation is that her physical suffering is largely dependent upon disturbed peace of mind. It is with difficulty that I have persuaded her to come to New York and see you. I feel convinced that you will succeed in bringing her back to a normal state, particularly if you gain her entire confidence and make her feel that she can rely upon you to listen understandingly to the complications of her life.

Apparently she has every worldly possession that goes to make life worth living, but the peace of mind surpassing wealth, which the Sage is said to find in meditation, eludes her.

After you have seen her I shall be grateful for a letter, telling me what you think of her condition. Don't hesitate to tell me if you conclude that it would be to her advantage to have me here, for I can easily arrange to return in the spring. I fear, however, that one of her own flesh and blood is not the best person to help her at the present time.

Yours very sincerely,

———

New York, Oct. 13, 1907.

My Dear Madam:

I have your letter of yesterday requesting an appointment for your sister. I hasten to reply so that you may have my view of your sister's case before you leave for your home, more particularly as I wish to get some further details from you before she comes to see me.

You have given me such a lucid account of your sister that I am able to say what her chief trouble is. Perhaps after receiving my reply you will think it

wise to take her to a priest, not a doctor. We really haven't made any advance in the treatment of jealousy since the time of Moses. In those days, when the spirit of jealousy came upon a husband or a wife, they were brought unto a priest, and it is probable that you can do no better than follow the example of the Israelites.

We who deal with disorders of the mind, as well as of the body, have sometimes to combine the offices of the priest and physician, but fortunately for the reputation of the clergy, we do not thereby arrogate to ourselves a comprehension of practical theology which surpasses that of men trained in that profession.

Jealousy is an instinct which we inherit from our animal ancestors. Those versed in biology and the laws of heredity do not hesitate to tell us with much confidence that it is an mnemonic engram, something almost as specific and material as a million dollars, but however this may be, no one denies that it is a heritage of animals and barbarism. It originates at a period in the development of the human species when possession depends upon might, and retention upon artifice and violence. It is an indirect effect or derivative of the most profound primordial passion. In other words, it is an irradiation of the sexual appetite which has a peculiar mental character.

In women it is less brutal and violent than in men, but what it lacks in these qualities it makes up in being more instinctive and more penetrating. Jealousy is like all other hereditary infirmities. It is very little influenced by what is commonly called treatment. To eradicate it requires the combined efforts of education and selection. These carried on for a sufficient length of time may gradually overcome it. As physicians, we have very little to do, unfortunately, with either of these activities.

I shall be glad to see your sister and listen sympathetically, and, I hope, understandingly, to her story. Perhaps I shall be able to suggest to her a line of conduct and a mode of thought which will bring into her life a greater amount of happiness. Except in a general way, however, it will be an experiment, because in every case in which disorder of the mind or of the emotions, flowing out of unhappiness, is the complaint, the indiidual and not the disease is what we have to treat. There are certain general principles underlying the treatment of such diseases as typhoid fever and pneumonia, but when it comes to the treatment of a state of mind which is the result of injustice—for I presume that everyone admits that jealousy is injustice—there are no cardinal principles.

I gather from your letter that your sister, besides being sensitive, romatic, and impressionable, is rather a literal person. She is, I presume, about thirty-five years old. The opportune time to attempt to eradicate those emotional qualities which are now contributing to her unhappiness has long since gone by. Not only is her character fully formed and set, but habitual modes of mental and emotional reaction to all sorts of stimuli have developed within her. She can scarcely hope to change this, save by prolonged mental discipline and toil. "For labor must lead the way to every fair possession, and he must toil who is eager to attain virtue. Thou knowest that Herakles and the Dioskuri, and Asklapius, and all other children of the gods, through toil and steadfastness accomplished the blessed journey to heaven. For it is not those who live a life of pleasure that make the ascent to the gods, but rather those who have nobly learnt to endure the greatest misfortunes." So wrote Porphyry, the Boswell of the Neo-Platonists, to his wife, Marcella, upward of fifteen centuries ago. I commend the letter from which this paragraph is taken to your sister.

Can you encourage me to believe that it will be possible to convince your sister that her experience is not unlike that of many of her sex, that in reality it is her lack of confidence or trust in her husband that precipitates her acutest misery and thrusts her into the injured lover's hell; that she does not make allowance for average human frailty; that she neglects to sum up the total of her husband's virtues and of his deficiencies and putting them in the judicial scale abide by the kick of the beam?

Furthermore, what shall I do if I become convinced that her husband's conduct is such as to justify resentment? Do you think it will be advisable for me to send for him and apprise him of my belief? Is it not possible that he will resent interference on my part, even though I put it on the grounds that his wife's health not only justifies but demands my interference? Moreover, I say to you now, frankly, that I may permit myself some latitude of professional privilege and advise her to apply for a divorce, for uncontrollable jealousy is, to my mind, a legitimate cause for such action. It might be well, therefore, for me to learn how the family look upon such a possibility.

I gather from your letter that you, who apparently understand your sister fairly well, and who have had much opportunity recently of seeing her, are of the opinion that there is some justification for her jealousy. But if her husband is a type of man that harks to no higher call than the gratification of his every desire, it seems to me that we cannot do much with such a person. What is there in him to which I can appeal that will be likely to influence him to shape his conduct more in conformity with his wife's wishes? I cannot believe that he is insensible to the fact that her complaints flow indirectly from his conduct. Is her health and happiness of such importance to him that he will be willing to make some sacrifice in order to secure them? You have not drawn him very clearly, and yet I feel that I must get an accurate description of him, in order to be of service to her. If you can tell me something of his conception of happiness, destiny, and justice, you will aid me in forecasting her future.

The only encouragement I can offer is that I may be able to give your sister, by suggestion, a mental attitude—a point of view—which in time may become a philosophy of life in which jealousy can be intellectually fought and conquered.

I need not tell you that there is scarcely any affliction so potent to cause misery and suffering as jealousy. Yet, what effort is made to eradicate it in the growing boy or girl who shows its warping effect and its baneful consequences? We take infinite pains and care to instil into the budding mind principles of honesty, veracity, chastity, and temperance. We expend any amount of energy in pointing out to our youth the advantages derived from learning to "play fair." We infuse them with sentiments of altruism, of unselfishness, of generosity—in short, with all the so-called humane impulses—but so far as my observation entitles me to an opinion, we do little or nothing towards teaching our youth that jealousy is more potent to produce misery and unhappiness in themselves and others than almost any other mental possession.

Suppose, for instance, that when your sister first began to feel the tentacles of this parasite fastening themselves upon her she had reasoned with her-

self, or had been reasoned with, to the effect that matrimony does not necessitate that either one of the contracting parties should cease to seek pleasure and diversion from association and honorable intimacy with persons of the opposite sex, and that so far as her information went such was the extent of her husband's guilt. Do you think she would have resolved, and fortified her resolution with whatever appeal to the supernatural her training and mental make-up suggested, to thrust jealousy out of her mind, as one throws out of his house a person who has attempted to impugn his honor and rob him of his best asset, integrity? Or do you think she would have been more likely to wreak vengeance upon the person whom she thought was trying to share some of her husband's attractiveness, a possession which she believes belongs to her exclusively? Is your sister a person who will be as frank and honest in discussing this feature of her affliction as you think she will be in laying before me her conception of the cause of her misery? From your knowledge of her, can you tell me if she has the capacity to take into consideration that not only is she concerned, but many others as well? I shall be able to find this out for myself, but your opinion in the matter will be helpful to me.

Perhaps you can also tell me something of your sister's interests, particularly what makes life for her worth living? Maeterlinck maintains that it is reasonable to believe that the paramount interest of life, all that is truly lofty and remarkable in the destiny of man, reposes almost entirely in the mystery that surrounds us; in the two mysteries which are the most dreadful of all—fatality and death. If this is so, and if your sister is so fortunate as to be a woman imbued with religious sentiment, it may be comparatively easy to give her a new point of view. She will accept, or, at least, make a serious effort to accept, that which is foreordained, believing that it has been initiated and sanctioned by the Infinite to which she bows resignedly. And if at first she cannot accept it fully and peacefully, silence and prayer and the religious attitude will facilitate its acceptance. If, however, her idea of life is—

> "To eat, to drink, and in communion sweet.
> Quaff immortality and joy,"—

the problem will be a more difficult one, but not necessarily insoluble. For if this life is all, then it behooves us to make it a success, to make ourselves and our associates happy, to spare no pains, to hesitate at no mental or moral operation which can reveal to us the art of living, and give to us and to those we love serene and beautiful days.

Correspondence.

THE INTERNATIONAL CONGRESS ON TUBERCULOSIS.

To the Editor of the Medical Record:

Sir:—The International Congress on Tuberculosis will be held in Washington from September 21 to October 12. With the exception of those of 1876 and 1887 it will be the first great international medical congress in the United States. There seems to be no reason why it should not prove a great success, and both the Americans, who planned, favored, and prepared it, and the Europeans, who have been taught to expect great things from America, are looking forward to the congress of 1908 as an event of the first magnitude.

Its objects are the study, prevention, and eradication of tuberculosis, the most formidable enemy of mankind, sapping its vigor and endangering its future. That is why in all countries both medical men and laymen have combined to search in the medical and social sciences for the root of the great evil, and are looking for its gradual extinction. That is also why educated and generous citizens have come forward with financial aid and mean to participate in the labors of the congress.

But, after all, a congress of this nature and with this program must be carried on mainly by the medical profession, and its objects cannot be realized without the cooperation of thousands. Now these lines have no other purpose than to draw the attention of the members of an ever ready profession, those who have forgotten or delayed, to the fact that only a few weeks more will pass before the congress will be opened. Meanwhile, the State of New York, the Empire State, had until a few weeks ago furnished less than five hundred active members. Five dollars sent to the Secretary-General, Dr. John S. Fulton, 1714 Colorado Building, Washington, D. C., will secure membership, including admission to the meetings and a copy of the Transactions of the congress. It seems that a mere reminder like this will swell the list of active members, whose duty and right appear to be to prove to the world at large, and particularly to those many foreigners who will visit us on this occasion, that America takes a prominent stand among the countries which value the health and the lives of their citizens. That is, Mr. Editor, why I take the liberty of requesting you to publish this appeal to my professional brethren of this and other States.

A. Jacobi, M.D.,
President, 4th Section, International Congress on Tuberculosis.

New York, August 3, 1908.

OUR LONDON LETTER.

(From Our Special Correspondent.)

CANCER RESEARCH—SANITARY INSTITUTE—TONE OF CARDIAC MUSCLE—HOSPITAL PRIZES, LONDON, GUY'S—OBITUARY.

London, July 17, 1908.

The annual meeting of the Imperial Cancer Research Fund was held on Tuesday, at which it was stated that the number of cases reported upon by the home hospitals after complete pathological examination now exceeds 10,000. The systematic experimental investigation of cancer is only of some five or six years' growth, and at the outset, as Dr. Bashford, the medical superintendent, points out, it was impossible to foresee along what lines it would advance, what animals would be most suitable for observation, and so on. Experience has taught much as to the requirements for the research and the scale on which observations must be conducted.

The executive committee reported that invitation had been received to join in the establishment of an international committee, but it was thought to be more advantageous to encourage an active interchange of views and material between the workers of the different countries. In pursuance of this policy the committee gave facilities for Dr. Gierke from Berlin and Dr. Russell from Aberdeen to work in the laboratories, which have further been visited by distinguished scientists from America, France, Germany, etc., who desired to learn the details of the organization and administration of the fund and the experimental processes employed in the laboratories. The expenditure of the year was over £14,700, exceeding the receipts by £1,443. The treasurer acknowledges the liberal assistance of the two Royal Colleges, which provided free accommodation in their laboratories. How far this may continue seems uncertain.

Sir Wm. Church moved the adoption of the report, referred to various portions of the work, and announced that full details would shortly be published in the "Third Scientific Report," which will differ from its predecessors by taking the form of seventeen separate, signed papers by the staff. It is three years since the second scientific report was issued, but results have in the meantime been frequently communicated to the Royal and other societies, in order that other workers in the same field might obtain them. Some of these I have communicated to you in former letters. Sir William drew attention to some of them, *e.g.* Dr. Bashford's, on the ethnological distribution of cancer, showing how fallacious are mortality returns as indicators of the prevalence of the disease, the number of deaths assigned to cancer increasing with the accuracy of the vital statistics of a country. The experimental study of cancer in mice and rats is based on the fact that inoculation gives rise to tumors characterized by the same powers of growth and tendency to dissemination as the spontaneous disease. The course in mice is closely parallel to what is seen in man. Spontaneous or induced, it does not at first interfere with general nutrition. The weight of a mouse increases with the growth of the tumor. In the later stages,

when hemorrhage or ulceration has taken place, diminution is found, and the mouse seldom lives above two weeks after loss of weight begins. As in man, removal is followed by a period of apparent recovery and the lost weight is regained. Recurrence is frequent—sometimes not for sixteen weeks, a considerable period in the life of a mouse. Metastases occur whether removal has been done or not, lending no support to the notion that operation favors metastasis. The failure of implanted grafts to develop seems to depend on the non-penetration of the graft by the tissues of the heart, and retrograde changes taking place for want of nutrition. No explanation of this appeared to Sir W. Church sufficient for acceptance. Absorption of normal mouse tissue appears to confer on mice a degree of immunity—special tissues to special forms, *e.g.* absorption of normal skin appears to give complete immunity to squamous-celled carcinoma; the absorption of tumor tissue increased resistance to inoculation of similar growths than to those with a different histological structure.

Mr. Butlin, in seconding the report (which was afterwards carried), referred to an objection that had been put forward as to cancer researches, that it had done nothing to solve the two great problems of cause and cure, and so was only of interest to the scientific world. He held that it was not a matter of indifference whether a surgeon called to treat a case held one theory or another. In his student days the humane pathology prevailed. The operators, therefore, did not hope to cure their patients, but only to afford some relief or prolong life for a few months. Before he began to operate the local origin was maintained by able pathologists, and surgeons began to operate with some hope. Accordingly, operations were better designed and more thoroughly performed. Nevertheless, until quite recently it could be argued that cancer was a constitutional disease. The result of our research has confirmed the theory of local origin, and has placed it on so firm a basis that he would be a bold man who would now maintain the older view. As a direct consequence of research, surgeons operate with a confidence which depends on a more accurate knowledge, and far greater success is attained. So, while anxiously looking for the discovery of an antidote, surgeons, Mr. Butlin declared, are profoundly grateful for what has already been done, and he had no hesitation in asserting that all the time, the labor, and the money which had been expended on cancer research are as nothing compared with the benefit which that research has already conferred on medicine and on the public.

The twenty-fourth congress of the Royal Sanitary Institute was opened at Cardiff on Monday. About 200 delegates were present. The Lord Mayor opened the exhibition of sanitary apparatus and appliances. The inaugural address was delivered by the Earl of Plymouth, who said sanitation meant comfort, health, and happiness for the people. It went a long way towards abolishing crime, immorality, and the evils that followed in their train. Inventions to keep microbes at bay ought not to be necessary. By leading healthy lives, in healthy surroundings, they could defy microbes. In newly-built houses provision should be made for open spaces and covered balconies for children to play on in the open air, instead of the dirty street. Women could sit there and watch them and work, and in summer such a space might often serve as a dining-room.

The section devoted to preventive medicine and sanitation was opened on Tuesday by Dr. Davies of Bristol, who urged that pathological and chemical laboratories should form an integral part of the medical service.

"The Tone of the Cardiac Muscle" was the subject of a paper at the Royal Society of Medicine by Dr. A. M. Gossage. He considers that probably the muscle is capable of two forms of contraction, that to which the term is usually applied and that which is to be distinguished as "tone." They may occur either separately or together. Nevertheless, he said, "tone" was never altogether absent, and on it ordinary contraction was, so to say, superimposed, but this was diminished by increase of contraction. Dilatation is due to loss of tone. Increased tone diminishes contractility, conductivity, and excitability. The action of cardiac toxics is chiefly to increase tone. Digitalis powerfully excites the muscle, increasing the rate of the rhythm; it also excites the vagus, and thereby diminishes the rate, but excites the tone. When contractility is depressed digitalis will increase the depression. Cardiac irregularity after digitalis is not due to increased excitability, but (1) a hidden irregularity may be unmasked by a diminution of rate; (2) extra systoles may be excited by the drug; (3) beats may be dropped out from depression of conductivity; (4) an alternating action of the heart may be caused, which is almost certainly due to depression of contractility.

Dr. James Mackenzie said that sudden dilatation of the heart was followed by an increase in its rate—a fact which might perhaps be explained by diminished tone lending increased excitability. Dr. Cushny said we must distinguish between toxicity and elasticity; the duplex action of digitalis, muscular and vagal, also. Decreased excitability was, he held, a vagal effect. Dr. A. Morison held to the nervous explanation of the action of digitalis; Dr. Cayley to the myogenic. Dr. D. B. Lees thought cardiac tone was in reality a spinal reflex.

This is the season for the distribution of prizes at the medical schools. I have sent you a note on one or two, and will now add others. At the London Hospital the function was combined with the unveiling of the statue to the Queen. The ceremony was performed by the Earl of Crewe. The statue is the first erected to Her Majesty, and is presented by the committee, staff, and a number of governors to mark the fact in the hospital's history that the Queen had consented to be its president, in succession to the late Duke of Cambridge, who had held that office for over fifty years. It further marks the appreciation of the deep interest taken in the work of the hospital by Her Majesty, who has paid many private visits to the wards, who in the dark days of the South African war sent out twenty-six of the nurses at her own expense, and came down to bid them Godspeed. To the Queen, also, the hospital owes the installation of the first Finsen lamp used in this country.

In distributing the prizes Lord Crewe said the British public did not know much about the schools, only seeing the splendid results. He told the students they were about to join the most noble of all the lay professions, and those who had not taken a prize might feel satisfaction at any honest work they had done to qualify them.

At Guy's Hospital Lord Rothschild distributed the prizes, and defended the claims of medical schools against some objections to making them an adjunct to hospitals. It had been said by some of these that the presence of students interfered with the comfort of patients, to which Lord Rothschild replied that this was not the case, and the students were often of the greatest service. He repudiated the idea that vivisection made them inhumane, and instanced the case of a friend of his, an old student, who being seriously ill, the workpeople of the neighborhood waited outside his door for news of his progress. The last objection noticed was cruelty to animals, as to which his lordship said anesthetics prevented suffering, and the benefits to humanity were so great that even slight suffering would not be sufficient cause for forbidding experiment.

Sir John Banks, K.C.B., died yesterday in Dublin, where he had spent a long and honorable career. He was physician to the King in Ireland and the first president of the Royal Academy of Medicine. He took M.D. at the University of Dublin in 1843, and became its Regius Professor of Physic in 1880, holding that office until 1898. He had also been president of the Royal College of Physicians, of which he was admitted a Fellow in 1844. He had received the honorary degree of LL.D. from Glasgow University, and D.Sc. from the Royal University of Ireland, on the senate of which he had served. The societies which delighted to honor him were numerous, and he was not only a leader of the profession, but of various institutions in the city. His clinical work was done chiefly at Sir P. Dun's and the Coombe hospitals, of which he became consulting physician, as also at the Royal Eye and Ear, the Richmond, and Hardwick hospitals. Among his literary contributions were "Typhus," in Quain's Dictionary, and various articles in the *Dublin Medical Journal* and the *Pathological Transactions.*

The death is announced from Brisbane of Sir Thos. Naghten Fitzgerald, F.R.C.S.I., 1884. He was born in Ireland in 1838, and qualified in 1857 from Mercin's Hospital. He went to Australia in 1858, and soon took a high position as surgeon, becoming at length senior surgeon to the Melbourne and consulting surgeon to St. Vincent's Hospital. He was president of the Victoria Medical Society in 1883 and 1889, and was also president of the Intercolonial Medical Congress. He was knighted in 1897.

Dr. Henry Ashby of Manchester died on the 6th inst. He took the M.R.C.S. 1873, M.B. Lond. the next year, and M.D., with gold medal, 1878. He became lecturer at Owen's College, and examiner at the university. As physician to the Manchester Children's Hospital he devoted himself to that department of medicine

with the greatest zeal, which was recognized by the American Pediatric Society creating him honorary member. He delivered the Whitmore lecture of the London Society; was elected F.R.C.P. in 1890. He enjoyed the confidence of the profession, and so had a large practice, but he found time to write several excellent works, among them the volume on diseases of children, jointly with Dr. G. A. Wright, which reached a fifth edition some two years ago. The journals and societies also received important papers from him. He was president of the Manchester Pathological Society in 1885-6.

Progress of Medical Science.

Boston Medical and Surgical Journal, July 16 and 23, 1908.

The Use of Fresh Animal Sera in Hemorrhagic Conditions.—T. Leary reports a series of cases of hemorrhage occurring variously in jaundice, the newly-born, and purpura, postoperative, uterine, typhoid, etc. He used rabbit serum exclusively. His series comprised 20 cases in all, in 15 of which hemorrhages had already occurred. In the remaining 5, the remedy was used as a prophylactic measure. Diphtheria antitoxin has been advised for hemorrhagic conditions and has been used to a slight extent, but to be of service in this connection it should not be more than two weeks old. The subcutaneous route is preferred for all the injections, 30 c.c. being the amount usually employed. The ordinary serum sequelæ may appear as usual. Of greater significance are the anaphylactic symptoms—sudden dyspnea, cyanosis and death—which may arise when a second injection or series of injections is made after an appreciable interval has elapsed since the first injection. This condition, common in guinea pigs, is rare in man. It is regarded as due to an increased sensibility to the toxic principles of the foreign serum, due to a sensitization of the body cells by a substance present in the initial dose or doses. Within an interval of ten days this danger seems to be absent. The author says that his series of cases is too small to permit the drawing of any conclusions, but he pleads for a wider use of the agent under the clinical conditions enumerated.

A Typhoid Carrier Fifty-two Years After Recovery.—Gregg's patient was a woman of 74 years who had had typhoid fifty-two years previously. She was a woman who had kept boarders, and whose house was clean and neat. Seven cases of typhoid presented one common factor, viz. that this woman prepared food for them all. Her blood was negative to Widal and her urine contained no typhoid bacilli but a plating of the fæces revealed a bacillus which responded to all the tests for the *B. typhasus*. No other evidence could be adduced that the seven cases had a common origin but it seems highly probable that this was the case. Similarly it could not be proven that this woman had been excreting typhoid bacilli all these fifty-two years but there was no history of a second infection.

Pustular Acne Heated with Staphylococcus Vaccine.—A man of 64 years under the care of B. D. Ridlon suffered from pustular acne of the nose for a year or so and did not improve. Various ointments and applications supplemented by constitutional treatment and the light treatment had been tried with little or no effect. His nose at time of admission to hospital was nearly twice the normal size, inflamed and covered with dried scabs and pustules. Cultures were made from the pus of some of the pustules which proved to be pure staphylococcus albus, and vaccines were obtained from these. May 26, 1 ccm. injected. This injection was followed by no physical signs except on the second day a marked improvement in the appearance of the nose. The inflammation had noticeably abated and the pustules had begun to disappear. Five days later improvement continued, nose had attained normal size and soreness had nearly disappeared; patient able to wipe his nose for the first time in months. In another week second injection of 1 ccm. Improvement continued and redness fast fading out. Eight days later third and last injection. Appearance of nose steadily improved until all signs of the disease disappeared except the scars of the pustules and there has been no recurrence to date (three months).

New York Medical Journal, July 25, 1908.

Expert Testimony and the Alienist.—W. A. White says that society has too long dealt with crime either from the standpoint of revenge—the principle of "an eye for an eye, a tooth for a tooth," is the principle upon which our criminal code is built and which controls much of its application even to-day—or from the standpoint of a disagreeable affair with which the easiest way is the best, and so it locks up the culprit, turns its back upon him, and tries to forget all about it. The time has passed for either one of these attitudes. Revenge may be sweet, but it is usually a pretty expensive indulgence. Crime is a social phenomenon and demands attention if for no other than economic reasons. It is distinctly an unwise policy that continues a system which actually makes criminals. What else can be expected when a young boy for his first offense is ruthlessly shut up in prison to associate exclusively for months with a collection of the worst and most incorrigible offenders? It is a distinct duty, pointed to by actual dollars and cents economy, to keep men out of prison, or if they get in to restore them to independence at the earliest possible date. These results will never take place until we learn to deal with the criminal and not the crime. This, says the author, would seem to be the rational method for the State to pursue. How best can it be accomplished? If insanity is the defense the defendant should be sent to the nearest State hospital for the insane. Surely if a person is insane the place for him is in an institution for the insane and not in a jail. Not only this, but only under the close observation possible in a hospital can the best results as to the diagnosis of the condition be expected.

A Note on Conjugal Diabetes.—A. C. Croftan has found six cases in a total of 241 diabetic patients. He quotes some statistics from other writers. In regard to the conjugal factor he says that it is clear that we are dealing in most of these cases with more than a coincidence; such a thing may occur by chance; but in his series, for instance, in which glycosuria was regularly looked for in the consort, the proportion of instances discovered is far too great to warrant the inference that this is the case. One must think of common errors of alimentation obtaining in a family, or of common errors of living, of exposure to common nervous, mental, and emotional influences. One must think finally of contagion. Syphilis and malaria can produce glycosuria; also certain other contagious and infectious disorders of known type that cause vascular degenerations in important organs (liver, pancreas, nervous system) concerned in sugar metabolism. It is not impossible that other infectious agents of unknown character and origin may be concerned in the transmission at least of certain types of diabetes. This subject is well worthy of further study; it is a corollary of the contagious theory of gout that is gaining many adherents. To deny the possibility of a contagious diabetes on the one hand is precarious; to affirm its existence on the other altogether premature. These facts and considerations at least warrant further investigation and the collection of more elaborate and more exact statistics. They have induced eminent authorities to commit themselves strongly in favor of the *reality* of conjugal diabetes.

Journal of the American Medical Association, July 25, 1908.

Fresh Air in Pneumonia.—T. W. Kilmer reports the results of the fresh air treatment in 16 cases of lobar pneumonia and 20 cases of bronchopneumonia in dispensary babies. Nearly every clinical type was represented, from mild to very severe, and the diagnosis was positive in every case. Many of the parents were ignorant, but willingly followed instructions and carried out the treatment surprisingly well. The treatment of both lobar and bronchopneumonia in these cases consisted in giving an initial purge (castor oil or calomel); mustard poultice to the chest; sponging to reduce fever; cutting down diet to one-half strength; hygiene of body, clothing, and sickroom, etc.; light expectorant every two hours for six to eight doses in twenty-four hours; keeping the gastrointestinal tract clear; abundance of fresh air; rest. One patient died, but not until the mother had insisted on taking the baby to a hospital; it is nevertheless included in the series. This makes the mortality 2.77 per cent., which is remarkably low for either private or hospital practice. The study, Kilmer thinks, shows conclusively that, by a combination of simple instructions to parents, and quiet, rest, proper food, and, above all, fresh air for the child, the mortality of one of the most serious diseases of infancy can be greatly reduced.

Diagnosis of Rabies.—J. B. Rucker has used the smear method of Williams and Lowden in the examination of thirteen cases for the Negri bodies, and described it as follows: A small piece of the gray matter of the brain is excised and placed on a clean slide near one end. The cut should be at right angles to the surface, only a thin piece being taken in order to avoid the white matter as much as possible. A clean cover-glass is placed over the tissue and pressed down with the thumb until it is thinly spread out, and with even pressure the cover glass is drawn almost to the other end of the slide. A little practice will enable one to thus produce a thin, even film of tissue. He used both the modified Giemsa stain and

also the modified Van Gieson stain as used by Williams and Lowden. The details of his thirteen examinations are briefly given, and he concludes, from his experience, that the smear method is preferable to all other methods, because: 1. It is much simpler than any other, on account of the extreme facility with which the smears may be made and stained. 2. It is much shorter than any other, requiring only from fifteen minutes to three hours. 3. In the smear method the Negri bodies appear very distinctly, and their minute structure is brought out very clearly. 4. The smear method is absolutely reliable.

Neurotic Hair Disorder.—L. D. Bulkley and H. H. Janeway recognize as neurotic and nutritive disorders of the hair the following conditions with their various etiologic varieties: Hirsuties, alopecia, canities, fragilitas crinium, trichorrhexis nodosa, alopecia areata, and monilithrix. The hair, they say, is an active, live portion of the economy, subject to various alterations dependent on its innervation and nutrition. The changes that occur in the hairy coats of sick animals would indicate this. There is a certain increase of activity of the hair follicles at puberty and a waning of the same in old age; fevers and nervous strain have their effects also on the hair. In 15,240 miscellaneous dermatologic cases in private practice a total of 1,129, or 7 per cent., were of the classes here considered. There were 175 cases of hirsuties in females, a condition not infrequent in insanity and at the menopause. The authors deem it probable that sexual derangements existed in a large proportion of these cases. Where facts were recorded menstruation was regular in only 22.8 per cent. There were nervous disturbances recorded in 31 cases. Six hundred and seventy cases of alopecia are tabulated according to ages; the most occurred between the ages of 20 and 22, and the great majority in males. Fevers, nervous disturbances of various kinds, debility, heat, daily use of shower bath, etc., were given as causes; in 182 cases no cause was assigned. In 22 cases it was ascribed to heredity. Thirty cases of canities are tabulated, three males and twenty-seven females. In four cases there was a clear history of nervous causes and in a considerable number the condition was associated with general debility. In one case of whitening of the hair in patches it was found due to leucoderma. The authors consider the reports of sudden and complete whitening of the hair from grief, fright, etc., as credibly attested. Twenty cases of fragilitas crinium, all but one females, are tabulated, and 32 of trichorrhexis nodosa, 26 of them females; little is known of the causation of these disorders, but Bulkley and Janeway think that they are more probably due to neurotic and nutrimental rather than parasitic causes. Alopecia areata is treated of at some length; it occurred 202 times in the 15,240 cases, in 1.3 per cent. of the total. In 10,000 public cases its percentage was only .06, or about half as much, a fact that speaks against a parasitic cause. Its spontaneous disappearance and its recurrence with nervous disturbances also indicate its constitutional nature, and its yielding to internal treatment while rebellious to local measures points the same way. It is more frequent in males, 199 of the 202 being of that sex. It is rarely seen in infants or after middle life, occurring most frequently between the ages of 20 and 35; in the youngest case of those here observed it began at the age of three months. While it sometimes disappears spontaneously or yields quickly to treatment, it is often very persistent. Several interesting observations made on these cases are given, indicating the constitutional nature of the affliction. Only one case of the rare condition known as monilithrix has been seen by the authors. While little is known of its causation, they consider a parasitic origin out of the question. In conclusion they insist on the practical importance of attention in these cases of nonparasitic disease of the hair to the constitutionl conditions and errors of living on which they depend. In almost every case it is found that if a physician has been consulted at all, there has been only some local application given, while in the large majority the trouble has been left to the hair dresser. Practically everything but the local condition has been ignored.

Pneumonia Diagnosis in Infancy.—R. G. Freeman insists on the importance of the clinical signs in the diagnosis of pneumonia in infants, and thinks that text-books, by laying too much stress on the physical diagnosis, tend to confuse the beginner. The physical signs are often not available in time to be of use. His conclusions are summed up substantially as follows: 1. Pneumonia in infants furnishes characteristic clinical symptoms on which a diagnosis may be based before the lungs are examined. 2. These symptoms are sudden onset, depression, rapid respiration with pulse ratio of from 1 to 3, fever and usually cough. If with these are observed flaring nostrils, pneumonic breathing and expiratory grunt, a definite diagnosis may be made, while rigidity of the neck and upper limbs, if present, is a valuable confirmatory sign. 3. Auscultation and percussion of the chest should be employed for confirmation of the diagnosis, for localizing the lesion, and for information as to its character.

Interstitial Keratitis.—A. E. Davis reports two cases of diffuse interstitial keratitis in acquired syphilis and remarks on the apparent rarity of the disease from this cause while it is so comparatively frequent in hereditary syphilis. He thinks that this rarity is more in literature than in actual fact, and that there must be many unreported cases. He reviews briefly some of the literature and gives his conclusions substantially as follows: 1. Diffuse interstitial keratitis may occur as the result of acquired syphilis. 2. It usually occurs as a late secondary symptom or in relapses in the tertiary stage. The average time of its development after the primary infection, is given by Stephenson as 10.8 years, but it has been reported as early as three weeks and as late as twenty-three years after the primary sore. 3. It is confined to one eye, though almost always a few exceptions to this are reported. 4. As a rule it runs a lighter course than the inherited syphilis cases, and rarely affects sight. 5. True "salmon patches" are rare in these cases. 6. It is difficult to make a clinical diagnosis between the tuberculous and syphilitic forms of the disease, and even a differential pathologic diagnosis is not always conclusive. 7. The prognosis is good, but it should be remembered that sight has been entirely lost in one reported case.

The Lancet, July 18, 1908.

Ascites in the Newly Born.—H. M. Inglis delivered a woman in her second pregnancy at full term and found the child's abdomen very much distended, being so tense that he could not palpate any of the abdominal organs. About 12 hours after birth the child passed a large quantity of urine, the abdominal tension becoming much less pronounced, the walls being slack enough to allow him to feel the organs. The heart sounds were normal. Death occurred 36 hours after birth. On postmortem examination he found a considerable quantity of bile-stained fluid in the peritoneal cavity. The omentum was so thin that he could not define it accurately. The intestines appeared to be covered with blisters, the largest being of the size of a walnut. As far as he could judge these blisters were little sacs of fluid on the under surface of a thinned-out omentum. All the organs were apparently normal. He attended this child's mother in her first confinement when the child died shortly after birth with a considerably enlarged liver.

Hemophilia in the Newly Born.—F. G. Brittin's patient was the child of a vi-para, an anemic woman who had always had severe postpartum bleeding. The reporter found the os fully dilated, the head presenting, the membranes unruptured and the caput succedaneum. The lumbosacral promontory was very prominent and evidently obstructed labor. Under chloroform he turned and brought down the child's right foot and delivered the child in five minutes without the slightest trouble. There was no undue traction necessary. On the next day he was asked to cut the child's frænum linguæ. It was very short, so he peeled it back with the finger to satisfy the mother. On the following day he visited the case and found that persistent oozing from the frænum had occurred since it had been peeled back. The whole of the frontal region was black, distended, and fluctuating. This swelling extended backwards over the skull and downwards behind the ears, which were pushed out. The skin as far as the clavicles was black. The right shoulder and arm were darkly ecchymosed and the right foot and leg were also darkly colored. On the next day the eyelids were black and the breathing was stertorous and the child died. The author believes that the extraordinary subcutaneous hemorrhage was due to some hemophilic tendency in the child.

Diphtheritic Paralysis Healed by Injections of Antidiphtheritic Serum.—After referring to several similar cases already on record, G. S. Middleton reports the case of a man of thirty-one years, admitted to hospital on account of paralysis. Eleven weeks before he had diphtheria and was in bed for four weeks. After a week in the country he tried to resume work, but was unable so to do owing to paresis of the limbs, preceded by vague pains and numbness in the hands and feet. The paralysis affected also his speech and deglutition. There was no ocular or facial paralysis, no dyspnea, and no palpitation. His legs gradually grew worse and he became unable to stand. Under bed treatment and electricity he failed to improve. Finally, after the paralysis had lasted nine weeks, serum injections were begun. Daily injections of 10 c.c. were made, and after 100 c.c. had been injected there was a slight but distinct gain in power. This was progressive and he gradually recovered his strength. By the end of the

injections he had an urticarial rash which appeared on the limbs and trunk and lasted for a couple of days, and was slightly itchy on the hands. Coincident with the rash was some puffiness of the eyelids and about the ankles, but there was no albumin in the urine. Occasionally he had pains in the calves of the legs and in the thighs of a neuritic character, but they did not trouble him much and had disappeared long before he left hospital. At no time had he any rise of temperature. The improvement that followed on the injections was so rapid in its occurrence and so marked that the author could not but attribute it to the remedy, though the objection might be raised that it may have been just when spontaneous improvement was about to begin that the injections were commenced. He was, however, impressed by the result.

Blood-pressure in Neurasthenic States and the Effects of Certain Forms of Treatment Thereon.—E. D. Macnamara presents the following conclusions: (1) In many cases of neurasthenia there is an alteration of the level of the blood-pressure from the normal, the level being sometimes higher and sometimes lower than normal. (2) Patients who show such alterations and who undergo certain sorts of treatment manifest, in some cases, at the end of a course of treatment, a level of pressure different from that which existed before treatment began. If the pressure at the commencement be abnormally high it will probably descend, while if it be abnormally low it will probably ascend. (3) The number of patients whose blood-pressure is different at the end of their course of treatment from that which it was before treatment began is greater among those without a family history of nervous instability than among those with such a history. (4) In a very large majority of cases the application of high-frequency currents produces a lowering of blood-pressure, while the static bath (+ charge) and massage produce a raising of pressure. The discharging of a patient charged with static electricity results as often in a rise as in a fall of blood-pressure. The application of the Faradic current tends rather to lower than to raise the blood-pressure and the galvanic current cannot be said to effect much change in either direction. (5) It is difficult to institute treatment with any confidence that there will be at the end of the course such an alteration as might perhaps have been expected from a knowledge of the alteration that is likely to follow each application of the therapeutic agent employed, though we may look for a change of level, when the level was at the commencement abnormal, to one that is nearer the normal. (6) There is no evidence that the differences of variation of level before and after treatment which may sometimes be noted can be correlated with improvement in health.

British Medical Journal, July 18, 1908.

Gonorrheal Iritis.—W. M. Beaumont says that the interval which usually occurs between the gonorrhea and the iritis probably explains the fact that the former as the progenitor of the latter is frequently overlooked. As a rule this secondary manifestation of the gonorrheal virus is rare. It is probably more apt to occur in those with a gouty tendency. Rheumatism is generally given the credit of etiology in these cases without apparent cause, but modern teaching bears in a contrary direction. The gout symptoms and eye symptoms are, more often than is generally admitted, both manifestations of a gonorrheal poison. Epitomized histories are given of twenty cases classified as iritis. Sixteen patients out of twenty confessed to gonorrhea, and, even allowing for the prevalence of the lues, this seems to be a higher percentage than can be accounted for by other theories than cause and effect. After due allowance for the circumstance that patients suffering from other forms of iritis, such as tuberculous, malarial, diabetic, etc., less often come to Bath (the city of the author's practice) for hydrotherapeutic treatment, he thinks it is fair to surmise that gonorrheal iritis is much commoner than some authorities are inclined to allow. The connection of iritis with rheumatoid arthritis is less clear, and he leaves it to others to say whether there is, in the first place, any connection whatever, and if so, in the second place, whether the iritis is the result of the rheumatoid arthritis, or whether it and the rheumatoid are both the offspring of some common ancestor.

A Little-known Type of Amblyopia in Children.—S. Stevenson gives the histories of six cases. He notes that a child may be brought for advice on account of poor sight, often discovered for the first time during early school life. In the hurry of an out-patient department it may happen that the underlying condition is assumed to be one of ordinary ametropia. The relative visual acuity is probably recorded, and atropin is certainly prescribed for home use. Later, a careful estimation is made of the child's refraction. It is then found that the absolute visual acuity, despite correcting glasses, can perhaps be brought no higher than one-third or one-half normal, while the optic disks are grayer than they should be. The ophthalmoscopic condition, in short, is one familiar to every physician as "post-papillitic" or "post-neuritic" atrophy. The atrophic changes, nevertheless, are not complete, and may, indeed, be so slight as to escape recognition in the absence of careful ophthalmoscopic examination. In the cases which it is the more particular object of this communication to describe the appearances are best characterized as those of "incomplete post-papillitic atrophy of the optic disk." They are, so far as the author has seen, invariably bilateral, although possibly sometimes more pronounced in one eye than in the other. Inquiry into the patient's personal history often elicits the fact that when an infant there had been a "cerebral" or "meningitic" illness, marked by such symptoms as "fits," convulsions, headache, vomiting, constipation, retraction of the head, temporary paralysis, squint, unconsciousness, and so forth. On recovery from the attack, sight was found to be partially or totally lost, but has since been more or less regained. The conclusion is almost inevitable that an infantile meningitis or encephalitis was accompanied by optic papillitis, and that both the general and local condition had to some extent been recovered from. The incomplete optic atrophy seen later by the ophthalmic surgeon, then, is on this view to be regarded as a sequel to a meningitic papillitis.

Berliner klinische Wochenschrift, July 13, 1908.

Hemolysins in the Pancreatic Juice.—Wohlgemuth says that the unactivated pancreatic juice has no hemolytic action while possessing strong lypolytic properties. If it is treated by the addition of enterokinase or of calcium chloride, or simply allowed to stand for some length of time, it acquires the property of dissolving red blood cells under certain conditions. The addition of lecithin alone is quite sufficient to call forth this hemolytic action, although no power of tryptic digestion is lent to the juice by such addition in the absence of the enterokinase. The newly acquired property of the juice is probably to be traced to the production of lecithins.

Münchener medizinische Wochenschrift, July 14, 1908.

Periodic Acetonemia in Older Children.—Hecker says that recurrent vomiting accompanying the increased acetone-content of the blood is a typical picture in the diseases of children caused by disturbances in the excretion of acetone bodies. Boys are usually affected; the attacks of vomiting occur periodically; the vomitus contains at first half-digested food, then becomes mucous in character, and may be tinged with bile or blood; no dietetic or medicinal treatment avails to stop the attack; great loss of strength and weight occurs in a very short time, and the patients suffer from intense thirst, not being able to retain anything in the stomach. The attack lasts two or three days and complete convalescence is followed by a recurrence which runs the same typical course. During the attacks the breath has the sweet, fruity odor of acetone, the urine contains the same body in abundance as well as diacetic and oxybutyric acids, which all disappear with the cessation of the vomiting. Hecker reports six cases of the diseases observed by him and expresses his conviction that the vomiting is a secondary symptom caused by the acetanemia and not *vice versa*. The therapy of the condition is not satisfactory. In some cases where the nervous element is present, suggestion is in place. Dry diet, with the use of chocolate and white bread may be used during the attack. The administration of alkalis proved to be of especial value, sodium bicarbonate or Karlsbad water being used. Systematic dietetic and hygienic treatment is called for between the attacks.

The Demonstration of Blood in the Urine.—Schumm says that the spectroscopic examination is the most reliable test for the presence of blood in the urine, the hand spectroscope devised by him allowing direct examination of dark-colored urines in sufficient amounts. Unchanged hemoglobin may be demonstrated in the urine if contained in the amount of 0.004 per cent., which equals approximately one drop of blood in the daily quantity of urine. For this purpose a polarization tube may be filled with the urine, the layer being 20 c.c. in thickness. The "tannin method" is very unreliable and shows blood in proportion of about 1 : 5000, or 0.02 per cent. The "coagulation method" is troublesome and incorrect in the presence of small amounts of blood. The "acetate of zinc" method is quite simple and reliable if a spectroscopic examination cannot be made. If the hemoglobin is changed to methemoglobin or to hematin, the pigment must be extracted before the spectroscopic examination is made. All the methods mentioned by the author are given in detail in the article.

Book Reviews.

THE DISEASES OF CHILDREN. A Work for the Practising Physician. Edited by Dr. M. PFAUNDLER, Professor of Children's Diseases, and Director of the Children's Clinic at the University of Munich; and Dr. A. SCHLOSSMANN, Professor of Children's Diseases and Director of the Children's Clinic at the Medical Academy at Düsseldorf. English Translation, Edited by HENRY L. K. SHAW, M.D., Albany, N. Y., Clinical Professor, Diseases of Children, Albany Medical College; Physician-in-Charge, St. Margaret's House for Infants, Albany; and LINNAEUS LA FÉTRA, M.D., New York, N. Y., Instructor of Diseases of Children, Columbia University; Chief of Department of Diseases of Children, Vanderbilt Clinic; Assistant Attending Physician to the Babies' Hospital. With an Introduction by L. EMMETT HOLT, M.D., New York, N. Y., Professor of Pediatrics, Columbia University. In Four Volumes, Illustrated in Black and White and in Colors by 61 full-page plates and 430 text cuts. Philadelphia and London: J. B. Lippincott Company, 1908.

THIS encyclopedic treatise on the diseases of children is the work of over fifty authors, each contributor having written on the part of the general subject of pediatrics to which he has devoted himself with special success. The first volume is given up to the broad general questions of pediatric art and science. A short chapter on the "General Pathogenesis and Pathology of Childhood" from the pen of Dr. Franz Hamburger is followed by an exhaustive symptomatology of the diseases of children, compiled by Professor M. Pfaundler, one of the editors of the work. This chapter takes up over two hundred pages of text, and recounts the various signs and symptoms of disease, classified according to the anatomical and physiological apparatus involved. Each sign or symptom is defined in a few words, and is followed by the various conditions in which it is met, many hints for differential diagnosis being added. A special index closes this compilation and increases very much its value for quick reference. Chapters on General Prophylaxis and General Therapeutics are followed by an article on milk by Professor Raudnitz; nursing, metabolism, and nutrition during the first year of life, children's growth in weight and height, and nutrition after the first year form the subjects of the chapters that close the first volume. Diseases of the newborn, constitutional diseases, and acute and chronic infections form the subject of the second volume, which contains contributions from such well known authors as von Noorden, who writes on diabetes mellitus and diabetes insipidus; Moser, who writes on measles; von Pirquet, who considers scarlet fever; and Schlossmann, the second editor of the work, whose subject is tuberculosis. The greater part of the third volume is concerned with the diseases of the digestive system, the authors of special articles being Moro, Finkelstein, Fischl, Pfaundler, Selter, Langer, and Stoos. This division of the work is of special interest to American readers, for it contains the latest theories and data of German research into the pathology of nutrition. Diseases of the respiratory and circulatory system and the special conditions depending upon the impaired function of the thyroid gland are the subject of the rest of this volume. Volume IV is devoted to diseases of the genitourinary and nervous systems, the latter part of the book being given up to the consideration of the diseases of the skin met in childhood. The contributors to this volume are Langstein, Pfeister, Zappert, Thiemich, Galewsky, and Leiner.

Each volume is provided with a special index of its contents, while a general index is found at the close of the last volume. The various articles are sufficiently illustrated, the pictures aiming to give the clinical appearance of disease rather than the pathological lesions. In general, the work is most valuable. It serves as a resumé of the progress in practical and theoretical pediatrics since the inception almost of this special division of medicine, and cannot fail to be stimulating to the worker in this field; reflecting as it does the teachings of the German school of medicine, its value to the American worker is especially great. The usual faults of a work from the hands of many authors could not, of course, be escaped in this treatise; the inequality of style, occasional repetitions, rather disproportional amount of space devoted to some subjects, all are present here, as in all similar publications. A more important fault of the book, however, is the omission of all references to the literature of the subject. Instead of such references the pernicious custom of simply reciting the names of authors who have written on some subject is continuously followed. Recourse to the "Index Medicus" usually shows that the author in question has written on a great variety of subjects and the reference is worse than useless; moreover, quite a few have namesakes active in other fields of medicine, and the "practising physician," for whom the work is intended, is compelled to hunt through other bibliographies to look up any special question.

There is little to be said in regard to the translation of the work. Anyone who has had experience in this field can appreciate the large amount of work done by the translators and the editors in bringing it out in the English language. They, as well as the publishers, are to be congratulated upon the success in rendering these important contributions to the pediatric literature accessible to the English-speaking profession.

LUKE THE PHYSICIAN, the Author of the Third Gospel and the Acts of the Apostles. By ADOLPH HARNACK. Professor of Church History in the University of Berlin. Translated by the Rev. J. R. WILKINSON, M.A. Edited by the Rev. W. D. MORRISON, LL.D. New York: G. P. Putnam's Sons, 1907.

THEOLOGICAL works do not usually find their way to the office of a medical paper. In the present instance, however, part of the volume deals with the question as to whether the author of two of the books of the New Testament was a physician. This chapter will be appreciated by cultured and educated readers; and the writer of the volume gives many interesting details tending to show that whoever wrote the Gospel of St. Luke and the Acts of the Apostles was unusually well informed in medical terminology. Several quotations are given from the original Greek, showing the use of technical medical words, and parallelisms are found in the work of the old Greek medical writers, Aretæus, Dioscorides, Galen and Hippocrates. In many instances these medical terms are found nowhere else in biblical writings, and often do not occur outside of medical literature. The Greek type is very clear, and the whole chapter will be read by many who would not care to undertake a larger and more thorough treatise on the subject, such as Hobart's work on "The Medical Language of St. Luke."

OPERATIONS-KURSUS AN DER LEICHE; anleitende Vorlesungen von A. BIER und H. ROCHS. Fifth Edition. Berlin: August Hirschwald, 1908.

THE fifth edition of this book now appears with Bier and Rochs as the authors, the former taking the place of von Bergmann who recently died. It offers in addition to a revision of the original text a description of several new operations, among others, Riedel's method of tying the subclavian artery, various new operations for cerebellar tumors, Killian's operation for frontal sinus disease, and the various incisions devised for appendicectomy. The general plan of the book for teaching purposes is excellent. The authors usually confine themselves to one or two methods of operating for the same disease, an arrangement always helpful to the student who does better to learn one method well than to attempt ten different ones. The book can be commended to the student and post-graduate before taking up a course of operative surgery on the cadaver.

TRYPANOSOMES AND TRYPANOSOMIASES. By A. LAVERAN, Membre de l'Institut, et de l'Academie de Médecine, Paris, and F. MESNIL, Chef de laboratoire à l'Institut Pasteur. Translated and much enlarged by DAVID NABARRO, M.D., B.Sc., D.P.H., Lond., Member of the Royal College of Physicians, London; Assistant Professor of Pathology and Bacteriology University College, London; Scientific Assistant in Pathology at the University of London; Royal Society Commissioner for the Study of Sleeping Sickness in Uganda, 1903. Chicago: W. T. Keener & Co., 1907.

IN 1904 Laveran and Mesnil published a very important monograph on the trypanosomata. This volume has been translated and greatly enlarged so that it is in some points practically a new work. The translator has himself contributed much to our knowledge of trypanosomes, and he has therefore been in a position to expand the text to the greatest advantage where the knowledge gained in the last three years has rendered any change necessary. The amount of new material may be judged from the fact that over two hundred new papers have been considered by the translator in addition to those studied by the authors originally. Owing to the possible relationship between the trypanosomes and the spirochetes a short section has been added on spirochetes of various types, including the *Treponema pallidum*, and also a discussion of the significance of the Leishman-Donovan parasites. Much new matter has also been introduced on the treatment of trypanosomiasis and concerning the culture methods, in which the important contributions of American writers have been fully acknowledged. A practically new chapter on tsetse flies and the trypanosomes which are found in them completes the work. Among the illustrations is an excellent colored plate showing different species of trypanosomes.

Die Röntgentechnik. Ein Hilfsbuch für Aerzte. Von Dr. F. Davidsohn. Berlin: S. Karger, 1908.

This short book contains a detailed description of all the apparatus and how to use it in *x*-ray work. The author shows how street, static, and storage current may be employed. One is made to understand the difference between hard and soft tubes and which quality of tube is to be used for the various therapeutic and photographic work; the time of exposure which will give the best results is carefully specified. The author lays special stress on how to avoid burns and sterility. All conditions amenable to treatment with the rays are mentioned. He emphasizes the diagnostic value of the fluoroscope and acquaints one with the errors liable to be made in interpreting photographic negatives. It is an ideal work not only for the general practitioner who wishes to become acquainted with Röntgen technique but also for him who may only be occasionally called upon to fluoroscope a patient or interpret an *x*-ray plate.

Movable Kidney and Other Displacements and Malformations. By David Newman, M.D., F.F.P.S.G., Surgeon to the Glasgow Royal Infirmary; ex-President, Glasgow Medico-Chirurgical Society; Late Pathologist to, and Lecturer on Pathology at, The Glasgow Royal Infirmary; Fellow of the Royal Medical Society of London. New York, Bombay, and Calcutta: Longmans, Green & Co., 1907.

This book is largely devoted to the record of observations and cases, and is illustrated by twenty-five diagrams and cuts showing the relations of the kidney and the different malformations and malpositions of that organ. The first chapter treats of the classification of the displacements and malformations of the kidney, and the normal anatomy. The next four chapters deal with the etiology, progress, symptoms, and physical signs, and the palliative and operative treatment of movable kidney. Characteristic cases are quoted, illustrating the different symptoms and types of movable kidney. The sixth chapter treats of floating kidney, while the last chapter deals with malformations and malpositions. Dr. Newman restricts the term "floating kidney" to those cases in which there is a mesonephron, and the kidney lies within the peritoneal cavity. The term "movable kidney" is applied when the organ is movable outside the peritoneal cavity. The book is well written. Each subject is considered systematically and thoroughly. It should be of use to the general practitioner in his management of those rare but troublesome cases in which the vague symptoms of a floating kidney are often misinterpreted and set down to the imagination.

Syphilis in its Medical, Medico-Legal and Sociological Aspects. By A. Ravogli, M.D., Professor of Dermatology and Syphilology in the Medical College of Ohio, etc. New York: The Grafton Press, 1907.

This work on syphilis differs from the usual monograph on this disease because the malady is considered from the viewpoint of the physician, the jurist, and the sociologist. A historical sketch of the search for the causal agent of syphilis opens the volume. The recent work on the *Spirocheta pallida* is briefly reviewed. The illustration of this organism, Plate I, is not extraordinarily good. Next follow chapters on the mode of infection, etc., and on the various stages of the disease. In the section on treatment a large amount of information has been collected and the details of all the methods now in use have been described. In the main the author follows the school of Fournier in his therapeutics; but many points are given from a vast individual clinical experience.

In the second part of the book the medicolegal and sociological aspects of the subject are dealt with. Here the author considers in an interesting manner the questions of syphilis and marriage; syphilis in relation to degeneracy; syphilis and public health and the regulation of prostitution.

Dr. Ravogli's book is a very complete and comprehensive treatise on syphilis written by a man who has made a life-study of his subject and who knows how to write a good clear English sentence.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles. Edited by W. T. Longcope, M.D., Philadelphia. Vol. IV, Seventeenth Series, 1907, and Vol. I, Eighteenth Series, 1908. Philadelphia and London: J. B. Lippincott Company, 1907 and 1908.

These two volumes of the International Clinics continue to keep up the general standard of excellence set by their predecessors. Among the contents of Vol. IV we notice an article on the Etiology and Treatment of Pulmonary Hemoptysis, by A. P. Francine, full of valuable suggestions for the practitioner confronted with this frequent and distressing symptom of tuberculosis. Professor A. Chantemesse gives his Five Years' Experience with the Use of an Antityphoid Serum; he had an average mortality of 3.7 per cent., while the general mortality of the disease in Paris reached 17.3 per cent. A. W. Hewlett contributes a scholarly article on The Common Cardiac Arrhythmias and gives the recent literature of the subject. Among other articles we find Surgical Syphilis, Perforation of Bowel in Typhoid Fever, Management of Pregnancy, Disorders of Sleep, and many others.

Vol. I, of the eighteenth series, opens with an authoritative article on The Sanatorium, by Lawrason Brown, which is illustrated with photographs and floor plans of the Adirondack Cottage Sanitarium at Saranac Lake. Dr. R. D. Rudolf of Canada gives his observations on the usual variations of temperature in the human being and questions the advisability of retaining on our clinical thermometers the line or arrow marking "normal temperature." Dr. Deaver speaks of the "Diseases of the Gall-bladder," Dr. Benjamin T. Tilton gives his deductions from a series of operations for perforated gastric and duodenal ulcers. Other articles discuss the care of the newborn, fracture of the spine, urinary acidity, etc., etc. The volume closes with reviews of the progress of medicine during 1907, Dr. A. A. Stevens writing on Treatment, Drs. David L. Edsall and Verner Nisbet on Medicine, and Dr. Bloodgood on Surgery. Most of the articles are extremely practical and up to date, and will save the practitioner much time and labor in acquainting him with the recent advances in medicine and surgery.

The Practical Medicine Series. Under the general editorial charge of Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Postgraduate Medical School. Volume I, General Medicine, edited by Frank Billings, M.S., M.D., head of the Medical Department and Dean of the Faculty of Rush Medical College, Chicago, and J. H. Salisbury, A.M., M.D., Professor of Medicine Chicago Clinical School. Volume II, General Surgery, edited by John B. Murphy, A.M., M.D., LL.D., Professor of Surgery in Rush Medical College (in affiliation with the University of Chicago). Chicago: The Year Book Publishers, 1908.

These are the first two volumes of this now well-known series of medical annals for 1908. The diseases referred to in the first volume are those in which special clinical or experimental work has been done, or notable advance made in the diagnosis or treatment. New signs and symptoms and rare cases are described. Tuberculosis and the diseases of the circulatory apparatus, and blood and blood-making organs are also thoroughly discussed.

The second volume has to do with the advances made in general surgery during the past year. The relative values and dangers of the various general and local anesthetics are discussed, and the technique, results, and dangers of spinal analgesia described. Space has been allotted to *x*-ray therapy, electrotherapy, new instruments, and the prevention and cure of postoperative vomiting. In the chapter on the diseases of nerves, cases are reported showing that in facial and infantile paralysis, even of long standing, there may be a restoration of function by nerve anastomosis. About 300 pages of the volume are devoted to abdominal surgery.

A Text-book of Clinical Medicine Treatment. By Clarence Bartlett, M.D. Professor of Medical Diagnosis and Clinical Medicine in the Hahnemann Medical College of Philadelphia; Visiting Physician to the Hahnemann Hospital. Philadelphia: Boericke & Tafel, 1908.

This is a work of over 1,200 octavo pages devoted entirely to the treatment of diseases. The author is a homeopath of the modern school who believes in the Hahnemannian principles and holds that "while the homeopathic application of drugs is the best in its results, we must bear in mind that medicines may be required for their palliative or mechanical effects." Accordingly he does not hesitate to give the salicylates the first place in the treatment of rheumatism, and quinine, in 15 to 20 grain doses, in that of malaria. In most cases, however, he gives preference to homeopathic remedies administered in the homeopathic way. An excellent feature of the book is the large amount of space given to a consideration of the dietetic, hygienic, and other nonmedicinal therapeutic measures. This feature is one that will render the work of service to practitioners of all schools, more valuable indeed than many of the treatises written by therapeutic nihilists of the regular school. The book will be found useful also by regular practitioners who desire to gain a knowledge of what intelligent homeopathic practice really is, but to whom the usual homeopathic handbooks of symptoms with their drug indications seem even more foolish than the "favorite prescription" manuals of their own school.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Twenty-Third Annual Meeting, Held in Washington, May 12 and 13, 1908.

THE PRESIDENT, DR. JAMES TYSON, PHILADELPHIA, IN THE CHAIR.

Tuesday, May 12—First Day.

President's Address.—Dr. JAMES TYSON of Philadelphia delivered this address. He became reminiscent, recalling former meetings, particularly the first meeting, twenty-three years ago, in the library of the Surgeon General's office. Dr. Delafield of New York was their first president, and in his address he said that all knew why they were assembled on that, the opening, day; it was because they wanted an association made up of representative men, men who would contribute something which would add to their knowledge; because they wanted a society in which they could learn something: that was the real object of inaugurating such an enterprise. The association had had printed twenty volumes; in them was contained much of the best work that had been accomplished during the past twenty-two years in the laboratories and clinics of both the United States and Canada. Dr. Tyson referred to the deaths of Dr. Charles Follen Folson of Boston and Dr. James Carrol of the United States Army, and gave a brief review of their lives.

Preliminary Report on the Result of Ligation of the Coronary Arteries in Dogs.—Drs. JOSEPH L. MILLER and S. A. MATTHEWS of Chicago made this report on experimental ligation of the coronary arteries in dogs with its bearing on the treatment of angina pectoris. Up to the present time the literature on this subject was not at all extensive. The results of their work so far had been quite uniform. After ligating one or more branches of the coronary artery in dogs the heart would cease to beat. Some investigators found that both ventricles stopped action at the same time. There was usually moderate bradycardia, with more or less arhythmia. When a large branch of the coronary artery was ligated, and the animal was killed from two to four weeks after, they found an area of necrosis in the ventricle which was very small compared to the area supplied by the ligated vessel. These animals, too, could live without giving evidences of any interference with the blood supply to the heart when the ligation was done at some distance from the heart. Hirsch and Spatleholz had concluded that the coronary arteries were not end arteries: that there was an anastomosis sufficient to allow the animal to live without showing any disturbance in the function of the heart. In 1884 Leyden declared that the cause of angina pectoris was an obstruction in the coronary arteries by a thrombus or embolus. Previous to that time the cause was given as neurotic. They attempted to produce in animals a similar condition to that which occurred in man. The first series of animals numbered nineteen, and a branch of the coronary artery was ligated, and the animals were allowed to live. On one group they tried nitroglycerin; on another group strophanthus. This enabled them to determine the amount of necrosis that occurred after ligation of the coronary arteries in dogs and the effect upon the area of necrosis of these various agents. The results had not yet been thoroughly worked out. Of the four animals that were allowed to live, three died a spontaneous death. Observations of the symptoms preceding death were only noted in one animal. This animal suffered from an intense dyspnea, and after its death they found an enormous dilatation of the right and left ventricles. The other animals were not observed at the time of death, yet the heart findings were similar to those found in the animal described. They probably died in the same way. In another group, of twenty-six dogs, an attempt was made to ligate the arteries successively until there occurred a marked disturbance in the heart's action. This was an incomplete systole of the left ventricle, an increased dilatation of the left ventricle and left auricle, then dilatation of the right ventricle and right auricle. Several branches were ligated successively until the animal showed signs of cardiac disturbances. These disturbances were treated with nitroglycerin, digitalis, or morphine. The nitroglycerin failed to restore the heart. When strophanthus was given intravenously almost immediately the systole became better until it reached the normal, the dilatation disappeared, the blood pressure even reaching a higher point than before the ligation.

Dr. WILLIAM H. WELSH of Baltimore said that this investigation should throw much light upon whether the intermuscular branches were terminal and the intercardial not. He asked Dr. Miller his opinion.

Dr. S. SOLIS COHEN of Philadelphia said that it was by no means certain that the lesions found postmortem represented the conditions present when the disease first manifested itself. They probably represented very largely the pathological results of the interference with the general nutrition through the coronary arteries, as well as other portions of the body. He believed there was a great difference between what was found in such experiments and what was found in the true disease; in the one the condition was permanent; whereas in the other it might be only temporary. In other words, the conditions between those necessarily fatal experiments and the conditions prevailing in the clinical course of the disease were so different that conclusions must be drawn with much reservation. The nitrites did exert a beneficial influence in averting paroxysms of angina pectoris.

Dr BABCOCK of Chicago said that at the present time he had under observation a patient, sixty years old, with a high blood pressure, whose attacks of angina pectoris were promptly relieved by the administration of nitroglycerin.

Dr. MILLER said he could not answer Dr. Welsh's query. It was interesting to note that the left ventricle stopped, while the right ventricle continued to beat for several minutes. In answer to Dr. Cohen he said that it seemed to him they were dealing with a transitory condition, and not exactly an obstruction of the coronary blood-vessel. Because it was transitory it did not mean, however, that they were not dealing with a permanent occlusion of the vessels. Whatever occurred in the heart, whether the condition was due to vasomotor spasm or to obstruction, it was a fact that they had to deal with an incomplete systole and a dropping of the blood pressure; therefore, the indication for treatment was to make the heart muscle better. Remedies should be given which improved the working power of the muscles of the heart.

Some Lesions of Experimental Nephritis.—Dr. H. A. CHRISTIAN of Boston spoke on this subject. Three lesions he had found in animals. First, a glomerulus lesion consisting of fine droplets, which were homogeneous, and which stained blue-black, these droplets occurring in the walls of the capillary tufts. The lesions were shown in photographs. They occurred in eleven of thirteen successive animals which received uranium nitrate in poisonous doses. Most of the animals were killed while in a toxic state. Only two out of the thirteen animals failed to show the lesions. Twelve other animals were used as control animals, each receiving other poisons, such as potassium bichromate, bichloride of mercury, Japan red, cantharides, etc. Of these twelve only two showed the lesions. Normal animals were studied as well, and in none were the lesions described found. Second, another lesion somwhat similar in structure, but occurring within the tubular epithelium. There were small hyaline droplets similar to the droplets found in some forms of acute nephritis, such, for instance, as followed scarlet fever. These lesions occurred when uranium nitrate was given. Photographs were shown of these lesions. Third, a

lesion that occurred mostly in the collecting tubules, and extended to the convoluted tubules. The tubular epithelium was distended with hyaline material, and there was as well a granular structure of the epithelium. There was a great increase in the thickness.

Concerning the Presence of Nephrotoxic and Hydrops-producing Substances in the Serum of Animals with Experimental Nephritis.—Dr. Richard M. Pearce and Dr. H. P. Sawyer presented this communication, which was read by title.

Review of Theoretical Considerations and Experimental Work Relative to Opsonins and Observations Made at the Saranac Laboratory.—Dr. Edwin R. Baldwin of Saranac Lake read this paper. He said that the original conception of opsonic activity as due to a distinct substance with independent functions had been modified by recent studies. Normal sera had been shown independently by Dean and Cowie and Chapin to exhibit a close parallel between opsonic functions and the reactions of normal amboceptor and complement to heat and absorption by bacteria. If not identical they were indistinguishable except in function. The phenomenon of phagocytosis was a physiochemical one. Immune opsonic activity was also closely related to immune amboceptors of bacteriolytic or cytolytic sera. There was a lack of correspondence in some particulars, and no necessary proof that opsonin was a distinct substance. Opsonic properties were also allied to agglutinative powers of sera, but were weakened more or less by complement. The weight of evidence was in favor of opsonins as amboceptor-complement in nature. Opsonic function as a measure of specific resistance was subject to limitations, but was applicable to mild infections. Recognition of specific opsonins in the diagnosis of tuberculosis as practised by C. P. Ritchie was referred to. The studies on the technique for the estimation of the index during past years had not increased confidence in its accuracy. The work at the Saranac Laboratory with inoculations of immune serum-opsonized tubercle bacilli had continued, and the results reported last year on rabbits had been confirmed. He reported the clinical work by Kinghorn and Twichell on the opsonic index in the diagnosis of tuberculosis by tuberculin. Their results did not encourage them to expect much practical use of the index in pulmonary cases in the usual method of its application. They had studied along two lines in the hope of obtaining comparisons between the normal and diseased individual which could be controlled with sufficient care to be of value. To this end they first estimated the tuberculo-opsonic index in sixty-three supposedly healthy individuals and thirty-six tuberculous patients, and always in comparison with the same normal serum. In the first it was found that the range given existed between 0.92 and 1.94 in health, taking a single normal as unity and including an unascertained extreme technical error of plus or minus 16 per cent. for a single test, or, according to Wright's standard, plus or minus 4 per cent., as an average. The mean of these normal sera was, however, 1.003. The index for the tuberculosis sera in five incipient cases ranged from 0.61 to 1.87; while in thirty-one advanced and far advanced cases, all with fever, it ranged from 0.26 to 2.26. They also made six or seven daily opsonic estimations before and after spontaneous tuberculin tests for diagnosis in seven persons. They obtained no regular growth, but the index was generally higher after the tuberculin reaction.

A Classification of Acidosis.—Dr. James Ewing of New York said that acid intoxication, or acidosis, occurred in diabetes, starvation, phosphorus poisoning, toxemia of pregnancy, cyclic vomiting of children, delayed chloroform poisoning, and many other diseases, in each of which the abstraction of fixed alkalies or the direct toxic action of salts of the acid compounds was supposed to contribute to or dominate the symptoms. The study of the pathological anatomy and chemistry of these diseases showed that there were two distinct classes of acidosis following two experimental prototypes: (1) Hydrochloric acid poisoning. Clinical forms: Diabetic coma; Kussmaul's coma; starvation. Pathological chemistry: Acetone compounds; ammonia proportional to the acids; amidoacid nitrogen slightly increased. Pathological anatomy: No lesions. (2) Extirpation of the liver, or Eck fistula. Clinical forms: Phosphorus poisoning; arsenic poisoning; toxemia of pregnancy; cyclic vomiting; delayed chloroform poisoning; acute yellow atrophy; pernicious anemia. Pathological chemistry: Lactic acid prominent; ammonia in excess of any fatty acids; ammonia primary; amidoacid nitrogen high. Pathological anatomy: Extensive fatty degeneration. Evidence was reviewed to show that these two types of acidosis were antagonistic in symptoms, origin, and pathogenesis, although combined forms existed. The urinary ammonia was accepted as the measure of acidosis, but there was reason to believe that its significance was quite different in the two conditions. The marked difference in the pathological anatomy of the two types was believed to further justify their separation.

Dr. David L. Edsall of Philadelphia said there was no doubt but that Dr. Ewing was right in pointing out these two classes of acidosis. It seemed hardly possible to attempt as yet, however, to indicate one type associated directly with lactic acid or other particular acids as causative of symptoms. In regard to the cyclic vomiting in children and such conditions, so far as their knowledge went, they could say nothing definite, or that there was an acid intoxication associated with it; but there was a general disturbance which might vary in type. An acid intoxication being a minor type, at the same time it might become so severe as to become an important matter. The ammonia question was also in decided doubt.

Dr. S. Solis Cohen asked Dr. Ewing what basis there was for estimating the amount or degree of acid or alkiline intoxication by the urine alone. It was certain that the alkali that was being excreted was not doing harm. He asked if there was not here a question of retention as well as the question of excretion. It had been proven that they might have an acid intoxication result from an excessive neutralization of the alkali, as well as the reverse.

Dr. Ewing said that in eclampsia they did get cases in which the ammonia was high, lactic acid only moderate in amount, and the acetone compounds absent. He wished to be understood that the classification presented by him was one looking towards the future. The toxicity of acetone was slight. The ammonia was looked upon as a compensatory process. At the same time the pathological and clinical indications were so clear that ammonia did have another significance that it inclined him to the view, although he was not able to prove it on chemical grounds. The acidosis was measured by the amount of ammonia in the urine, an indirect method, and the amount of acid required to neutralize it.

Experiments with an Ash-free Diet.—Drs. Elliott P. Joslin and Harry W. Goodall of Boston presented this communication. Two healthy men were fed on Taylor's ash-free diet (whites of eighteen eggs, 200 g. of crystalized sugar, 120 g. olive oil, freed from salts) until the daily excretion of chlorine was less than 0.3 gram. No symptoms of acid intoxication appeared, and at no time was acetone detected in the breath or urine. A marked loss of weight occurred, which was regained in the first experiment within four days after a return to an ordinary diet. In the second experiment the weight was nearly all recovered in three days, with the individual remaining on the same ash-free diet, plus 12 grams of salt daily. The assimilation of food was excellent. There was a marked diuresis, 4090 c.c. of urine, which occurred in the first case four days after a return to a regular diet. A third observation was made upon a case of diabetes with a minimum carbohydrate balance of over 50 grams. The chlorine in the urine gradually fell to less than 0.3 gram in twenty-four hours, but the change in acidosis was

insignificant and the condition of the patient was better than for some days.

Dr. D. L. Edsall of Philadelphia, Dr. James Ewing of New York, and Dr. E. P. Goslin of Boston discussed this paper.

An Unusual Paroxysmal Syndrome, Probably Allied to Recurrent Vomiting, with a Study of the Nitrogen Metabolism.—Drs. Theodore Janeway and H. O. Mosenthal of New York presented this communication. A school girl of sixteen, with no neurotic inheritance, had been subject to recurring attacks of a peculiar nature since infancy. These attacks formerly came every one to four months, but for a year increased to once a week for three months with absolute periodicity. Description of previous attacks tallied absolutely with those observed. The attacks began with epigastric discomfort, increasing to real pain in four to six hours, and severe abdominal pain, with pain in the shoulder, hips, etc., in eight to twelve hours. There was loss of appetite and salivation from the onset. In six to twelve hours the temperature began to rise and pulse became rapid, reaching their maximum in about four hours. As much as 104° and 140 pulse had been noted. Nausea, retching, and usually vomiting once or twice occurred at height of attack. Tongue was thickly coated and breath heavy, but not sweet. Abdomen was rigid and tender, most to right of umbilicus. The whole febrile period was eighteen to twenty-four hours, and, as a rule, in less than thirty-six hours she felt well and ravenously hungry. Marked polynuclear leucocytosis accompanied each paroxysm observed, with subsequent leucopenia for a few days. Weight was rapidly regained after the attack. Saliva was always acid. Vomitus contained abundant free HCl; stomach contents between attacks somewhat excessive HCl. Urine usually showed a trace of acetone, unrelated to the attacks, otherwise nothing. Metabolism study on a purin-free diet showed very little deviation from the normal, but uric acid was markedly decreased and ammonia somewhat increased with two attacks. A further study after a lapse of three months was now under way. Purgation, lavage of stomach, diet, all were without influence on the attacks. There was marked decrease in number and severity after period of observation with use of the alkalies; but renewed severity occurred later. The condition seemed most probably a toxemia allied to the recurrent vomiting of children.

Dr. Walter B. James of New York, Dr. Edsall of Philadelphia, and Dr. E. P. Joslin of Boston reported similar cases.

On the Relation of the Parathyroid Glands to Calcium Metabolism and the Nature of Tetany.—Drs. W. G. MacCallum and Carl Voegtlin of Baltimore made this report. They said that the convulsive and other symptoms of tetany which resulted from the extirpation of the parathyroid glands might be made rapidly to disappear by the administration of a soluble salt of calcium. This result was most quickly attained by the intravenous injection of the salt, but also followed its administration by mouth. Studies of the metabolism of dogs in tetany showed an excessive output of calcium, and the blood and tissues were found to contain a diminished amount of that substance. It seemed probable that the parathyroid glands exercised a control over the calcium metabolism, and that the loss of calcium from the brain and other tissues resulted in the phenomena of tetany.

Dr. John H. Musser of Philadelphia reported a case of adenocarcinoma which involved the thyroid and lymphatic glands and other structures in the neck. An operation was required to avoid strangulation and the parathyroids were removed. Five days after the operation tetany set in and pursued the course as noted in artificial tetany. There occurred an oppression and distress in the lower part of the abdomen and a band-like constriction, tremor of the tongue which was followed by the usual phenomena in the extremities, with the associated and well-known phenomena of tetany. This patient was given large doses of calcium lactate; as a result the symptoms were relieved, although morphine had to be given for a time as well. With the absolute cessation of the tetany the calcium salt was withdrawn, and, at the end of from forty-eight to seventy-two hours, the symptoms recurred. Again the administration of calcium lactate caused a cessation of the symptoms. Dr. Goodwin made a study of the urine during and after these attacks, and would report upon his findings later.

Dr. S. J. Meltzer of New York reported a case that occurred in the hands of Dr. Charles A. Elsberg of New York, the tetany following an operation for harelip. It was a case of tetany, and not one of tetanus. Calcium lactate was administered by mouth, and all the symptoms subsided in one or two days. The calcium lactate was then omitted and the symptoms returned. The salt was again given, and the symptoms again disappeared. This certainly showed that calcium exerted some influence on tetany. Dr. Meltzer said that the absence of calcium salts seemed to increase the irritability. He reported an experiment in which an animal was put into coma of an extreme degree by a magnesium salt. When calcium salt was introduced afterwards, in from fifteen to thirty seconds the animal was up and walking around. Calcium was capable probably of keeping up the balance of the inorganic salts. The effect of sodium, potassium, or magnesium was to produce either an increased or a diminished irritability; but the addition of the calcium salt caused a reestablishment of the irritability in both directions.

Dr. D. L. Edsall of Philadelphia reported a case of myasthenia gravis in which improvement followed the use of the calcium salt. Cases of acromegaly, and conditions associated with acidosis, were benefited by the administration of the calcium lactate.

Some Cases Presenting a Recurrent Syndrome, Apparently Due to Exposure to Heat.—Dr. D. L. Edsall of Philadelphia said that in 1904 he described two cases which were at the Episcopal Hospital, and in which he was struck by the puzzling clinical picture, which so closely resembled tetany. The condition was not accompanied by any increase in the reflexes or changes in the sensations which would indicate a central origin. These two patients had been exposed to an intense heat, one atmospheric, the other from fire. Last summer Dr. Edsall met with two more cases, much milder but of similar type. In these the same symptoms could be brought out by mechanical or electrical irritation of the muscles. Both men were firemen on stationary engines. He learned that the trouble was very common among firemen. He made quite an inquiry among those in the shipping service and locomotive firemen and iron workers. A description of this condition was seldom seen in the medical literature; in fact, he found but one short paper dealing with the subject. Exposure to extreme degrees of heat produced this condition, and he found it to be quite a common thing. The chief symptom was cramps, especially in the extremities, and resembling somewhat tetany, but which was not accompanied by the characteristic symptoms of tetany. He was told that in the navy from 400 to 1,000 cases occurred every year. Even deaths had occurred from this disease within one or a few hours after the onset of the symptoms. In the merchant marine service it was very common, because the men there worked under forced draught. He thought that probably it was toxic in origin. It might be due to an intense nervous irritation caused by the heat.

Non-fatal Coma in the Course of Diabetes.—Dr. C. N. B. Camac of New York reported a well marked case of diabetes occurring in an adult, observed for three and a half months, after which there was an onset of coma with marked urinary changes. The coma (not the Kussmaul type) was fully developed. Alkaline treatment was instituted, and only small doses were required to alkalinize the urine. The duration of the symptoms was one week. Recovery from the coma followed, and the urinary findings were as before the coma. Four months after the

coma hemiplegia occurred and death without coma. Dr. Camac said there were three distinct clinical subdivisions of coma, the Kussmaul, the alcoholic and the diabetic collapse, that were well known. This was but a single case; but it did not occur very often in their experiences to have a non-fatal case of diabetic coma which went to complete recovery, the patient dying of another condition, as shown at autopsy. There were found a chronic nephritis, cerebral softening, and a general arteriosclerosis. Whether the oxybutyric acid had anything to do with the production of these cases was still a question unanswered.

Dr. S. Solis Cohen of Philadelphia recalled a case seen in the early days of his practice. A woman had had diabetes fifteen years before she came under his observation and died twenty years later suddenly. She recovered from her diabetes and died twenty years after. The sugar had disappeared entirely from her urine five or six years before her death and was replaced by albumen. Her symptoms before death pointed to angina of the epigastric form. She was seventy-two years of age at the time of her death. He resorted to large quantities of alkalies by rectum and hypodermocylsis, and the urine was always kept alkaline in reaction. Sodium bicarbonate was taken in sufficient quantities to maintain the alkalinity of the urine.

He reported a second case, with equally marked symptoms and with an equally marked recovery. The woman was one of two sisters under his care for diabetes. The sugar disappeared under treatment, and she returned to a distant city where she lived. There she became careless as to her diet, and a condition of diabetic coma began to develop. She died three or four hours after her arrival in Philadelphia. The other sister had been ill with diabetes for ten years, and the sugar never entirely disappeared from her urine. She now was suffering from a stone in her kidney, as revealed by the *x*-ray. She had coma, from which she recovered. The symptoms of coma came on gradually. It was impossible to make the urine alkaline by anything given by mouth and, therefore, he used hypodermoclysis, and the patient made a recovery. This was one year ago, and she was still living, but had as much sugar as before. In this case the ammonia content was not increased.

A Study of the Atrioventricular Bundle, with Report of a Case.—Dr. Walter B. James of New York made a presentation of a specimen showing an ulcer on the interventricular septum completely cutting across the atrioventricular bundle, with complete dissociation of auricles and ventricles. More definite definition and limitation of the term Stokes-Adams syndrome should be demanded, with a discussion of cases simulating and often wrongly diagnosed as heart block. He suggested a possible atrioventricular delay as early evidence of acute myocarditis.

The Intraventricular Systole.—Dr. H. A. Stewart of Baltimore said that the development of pulmonary insufficiency when there was an increase of the pulmonic pressure, and its disappearance with the readjustment of the pulmonary circulation, had pointed to the important action which the pulmonary musculature must have in maintaining the competency of the valves of the artery. Similarly, in the case of aortic orifice, while it was not common, it was by no means rare, to note the disappearance of a diastolic murmur with an amelioration of the cardiac action. Clinically, he had noted the latter in cases of exophthalmic goiter, and experimentally in dogs when a diminution of the cardiac tone was produced. In view of these facts they were led to make a study of the action of the ventricular musculature surrounding the aortic orifice in dogs, in order to determine to what extent the valvular incompetency was dependent upon muscular action. For this purpose they devised an instrument by which the contraction of the ventricle internally could be recorded. The approximation of the opposing walls of the ventricle at different points from apex to base were noted. Special study was made of the sphincter-like muscle which surrounded the aortic outlet. This muscle had long been recognized, and was well described by MacCallum in Welsh's Festschrift (1900). The results of the investigation were, in brief, that the cavity of the ventricle was contracted first at the apex, the contraction passing upwards along the base. The contraction at the outlet appeared to be more complete than elsewhere. The contraction of the muscle mentioned above, viz., the aortic ring muscle, was prolonged into diastole.

Heart Sounds Heard in Early Diastole.—Dr. W. S. Thayer of Baltimore said that years ago he reported the results of some observations made upon dogs' hearts, and then mentioned that he had heard a third sound occurring after the second sound. It sounded like a snap. Many normal human beings had such a sound, which was quite audible, and in normal hearts. It was strange to him that such a sound had not been mentioned in the literature. This fall he came across one or two dogs showing the same sound in an apparently normal heart. Case I. This dog had a dilated heart. The third sound was present. The sound disappeared upon the administration of large doses of strychnine. Case II. An interesting point in this animal was that it showed a slight hitch at the beginning of diastole. His observations led him to think it might be interesting to go back over the human cases, as well as dogs, to determine the frequency of this sound in normal cases. During a period of four months he had taken the cases as they came to him in his consulting room and in the wards of the hospitals, and he said he had heard upwards of thirty instances of third sound in perfectly normal hearts in normal individuals. This sound was a soft sound, distinctly audible, and increased when the individual was upon the left side. This sound had been noted by certain men abroad. It was impossible to say to what it was due.

Dr. Augustus A. Eshner of Philadelphia discussed these cases.

A Study of Three Cases of Anemia in Children.—Dr. M. H. Fussell of Philadelphia reported these cases.

Case I. This patient was a boy, thirteen years of age. No venereal history could be obtained in either parent. The child had been breast fed, and during his entire life had had intestinal disturbances. When three months old he began to get pale and there was noted a tumor in his abdomen. Shortly before his death he had a marked enterocolitis. There was a very large splenic tumor. The boy died suddenly during an attack of vomiting. At autopsy all the tissues were found to be extremely palid and, with the exception of enlarged mesenteric glands and an enlarged spleen, there was absolutely nothing found pathologically. The blood examination showed 30 per cent. hemoglobin; 2,834,000 red cells, 56,400 whites. There was a 70 per cent. polymorphonuclear count, 6.8 per cent. small lymphocytes, 1.4 per cent. large lymphocytes, and 12 per cent. myelocytes. There were a few nucleated red cells. Histologically practically nothing was found except a hyperplasia of lymphatics in the spleen and enlarged lymph glands. There was some thickening of the blood-vessels. There was no sign during life or at autopsy of rickets.

Case II. This patient was a girl, seven years of age. There was no history given except that the child had vomited blood a number of times. She had been weak and pale, and she entered the hospital with all the physical signs of anemia, with enlarged heart and marked presystolic and systolic murmurs. There was also fever. There was no leucocytosis. He thought there might be a septic condition of the endocardium. This patient died after a large hemorrhage from the stomach. Just before death the hemoglobin was 20 per cent., the red cells numbered 1,376,000, the whites 6,000. The polymorphonuclear count was 60 per cent. At autopsy the liver was found to be enlarged, pale, and pinkish. The spleen

was large, pale, and smooth. At the cardiac end of the esophagus there were a number of dilated veins, and the bleeding occurred there.

Case III. No history could be obtained in this case, except that the child had suffered for three months. The patient was lemon-colored, and she gave distinct signs of rickets. The spleen was very large, reaching to the symphysis. The liver was felt one-half way between the xiphoid and the umbilicus. The hemoglobin was 24 per cent., the reds numbered 1,600,000, the whites 24,160. The polymorphonuclear count was 40 per cent., the small lymphocytes 4 per cent., and there was 2 per cent. myelocytes. The spleen capsule was trabeculated, but not increased in thickness or density. The Malpigian bodies were small. The lymph gland follicles were large. There was a slight endothelial increase. There was a moderate fat infiltration, especially in the periportal area. A cellular infiltration was found in the kidneys.

Splenic Anemia, Splenectomy, Recovery.—Dr. Morris J. Lewis of Philadelphia reported this interesting case. A study of the blood was made, which covered a period of seven years, four before and three following the operation. Slight enlargement of the spleen was first detected in 1900, with a gradual subsequent increase in size until in 1904, the year of operation. There was a moderate anemia of four years' duration, followed by profuse hematemesis, and by melena, which occurred shortly after an examination which proved the blood to be practically normal, viz., hemoglobin, 90 per cent. red cells 5,000,000, white cells 6,100. There was a rapid fall in hemoglobin to 18 per cent. and red cells to 1,100,000. There was a history of indigestion of long continuance. A gastroenterostomy was performed, on the theory of a possible gastric or duodenal ulcer, followed by a gradual gain in health, and practical cessation of melena. He asked if this gain was due to an accidentally performed Talma's operation, brought about by adhesions, or to an enforced quiet of the stomach. Splenectomy was done in 1904, four months later. An accurate study of the effects of splenectomy on the blood changes interfered with by inflammatory complications, viz., pleural effusion, pericarditis, and abscess in wound, was made. The high total leucocyte count immediately after the operation and during the time of complications, reaching 24,000 per cm. and rapidly falling during the convalescence to an average of 10,000, which average was still maintained, was recorded. Eosinophilia immediately after the operation was apparently modified by the complications, but reached its highest point, 1,300 per c.mm., two months later. Eosinophilia still persisted, three years after the operation, 570 per c.mm. There was but little change in the lymphocytes.

Dr. James B. Herrick of Chicago said that two years ago he examined a man, nineteen years of age, who was suffering from a pneumonia, and he noticed a scar in the abdomen and asked its cause. The patient, although slightly delirious, replied that a surgeon made it in operating for a tumor of the spleen. After he had passed through his pneumonia he inquired into details, and learned that, when thirteen years of age (six years prior) he had suffered from gastrointestinal disturbances, particularly from diarrhea. There was an enlargement in the abdomen, and a surgeon was consulted. The further details of the case were given by Dr. Oschner of Chicago, who confirmed the previous history given by this young man. The diagnosis was a primary splenomegaly, a splenectomy was performed, and the patient survived the operation.

Dr. Blackader of Montreal reported another successful case of splenectomy.

On the Relation of Urobilinuria to the Presence of Bile Pigment in the Blood.—Dr. L. A. Conner and Dr. J. C. Roper of New York presented this communication. Dr. Conner said that they had attempted to throw some light upon the perplexing subject of the source of the urinary urobilin. By the use, in a large number of pathological cases, of a clinical method of determining the presence and the amount of bile pigment in the blood serum they believed they had been able to demonstrate that, in most cases at least, the existence of urobilin and its chromogen in the urine bore a direct and quantitative relation to the presence of bilirubin in the blood; and that in such cases no urobilin was demonstrable in the blood. An exception to this rule had been found in the case of certain pneumonias in which, although no bile pigment could be detected in the blood, urobilin was present in both the blood and the urine. A possible explanation for this peculiarity was in the action of the pneumococcus. Again another possible explanation was that the urobilin might come from a reduction of the bile pigment, caused by the pneumococcus.

The Relation of the Auditory Area to Aphasia.—Dr. Adolf Meyer of New York said that Nature's experiments with man were largely injuries, vascular lesions and the like, that was, very coarse interference almost inevitably subcortical as well as cortical. Similarly the convolutional patterns commonly used in descriptions were far from allowing sufficiently reliable specifications. Descriptions were especially loose, and therefore interpretations difficult for the temporal lobe in which the essential receiving station was hidden, and therefore usually poorly described or pictured. The study of the cases of sensory aphasia in the collection of the Pathological Institute of the New York State Hospital showed: (1) The possibility of easy and efficient reconstruction from serial sections, rendering accurately the relation of the lesions to both the fiber paths, and especially also to define cortical areas, which were as easily demonstrable in the adult as with Flechsig's method in the infant's brain. (2) The probability that the extent of the lesion of the narrower auditory zone (the transverse temporal gyri) and its fiber supply went parallel with the extent of auditory word-imperception.

Observations on the Pathology of Exophthalmic Goiter, as Related to Clinical Symptoms.—Dr. Louis B. Wilson of Rochester, Minn., read this paper, illustrating it with lantern slide projections.

Erythromelalgia, Raynaud's Disease, and Allied Conditions in Their Relation to Vascular Diseases of the Extremities.—Dr. B. Sachs (in association with Dr. L. Buerger) of New York said that from a study of twenty cases it was proposed to show that these disorders could not be maintained as distinct clinical entities; that they constituted in the majority of instances symptom-groups merging into one another, and often representing varying degrees of the morbid process in the blood-vessels. Dr. Buerger's studies on the pathology of the blood-vessels in these conditions proved that the pathological process was not an obliterating endarteritis, but an obliterating thromboangeitis.

Wednesday, May 13—Second Day.

Report of Two Cases of Relapsing Fever, with Demonstration of the Spirochætæ in the Blood of Patients and of Inoculated Rats.—Drs. John W. Hunter and Thomas A. Cope of Philadelphia presented this communication. The paper consisted of a brief historical review of the disease, with a short *résumé* of the recent work done on the subject, including serum studies. The first case was imported from Europe, and the second patient, who had lived in this country for over a year, acquired the disease through sleeping with the first patient after he had developed fever. Both patients were natives of Turkey.

The Therapeutics of Self-repair.—Dr. S. J. Meltzer of New York read this paper. He said that numerous facts in biology justified the conception that the living organism represented a mechanism and was in very many respects comparable to a complex human-made machine. The efficient repair of a mechanism of a human-made

machine justly presupposes a familiarity with its normal structures and construction and also a complete understanding of the nature of the disorder. But what was the status of our understanding of the living machinery and its disorders? Well might we point with pride to the great strides we had recently made in this understanding. However, the actual extent of our knowledge, it must be admitted, was very small, and was only an infinitesimal fraction of that knowledge which would enable us to comprehend the living machine as a competent engineer understood the human-made machine. While no man would be permitted to meddle with some serious disorders of the human-made machine with only a fraction of knowledge of its construction, with the disorders of the mechanism of life for thousands of years millions of men meddled with their repair with a knowledge infinitesimally small indeed, even when compared only with the present-day understanding of the processes of life and their disorders. No man could doubt what the outcome would be in an ignorant meddling with the human-made machine; it would lead in the great majority of cases to its complete destruction. But with the human organism no such disastrous results followed the innumerable ignorant meddlings with its disorders. The truth of the matter was that with just regard to therapeutics the living animal body ought not and could not be compared with an artificial machine. No machine had yet been invented which could automatically repair its own disorders. The living organism, however, was well provided with such automatic arrangements for self-repair. He said there were two methods of treatment which competed in the past in the domain of internal medicine, the rational and the empirical, the former possessing only negative virtues, leading essentially to inactivity, the latter satisfying its followers by the activity to which it inspired. Many ailments and diseases terminated spontaneously in recovery; therefore it was evident that the animal organism must possess means and methods by which it accomplished these recoveries. Here, then, a competent school existed where therapy could be learned legitimately and efficiently. With this object in mind, the method of self-repair of the animal body becomes the object of profound scientific studies, and immunity became the third method of therapeutics. Dr. Meltzer said he feared that the aspect of the studies of immunity was not yet appreciated even by some of the leading pharmacologists. It was a good thing that the antitoxins were discovered; here was something which physiology could not claim as its own and pathology had not yet laid hands upon it. Here was something which the body in its efforts of defense and repair evidently manufactured anew. The present tendency in pathology was to consider every symptom as a manifestation of the efforts of the organism for defense and self-repair. All the signs of inflammation were now considered as factors in self-repair. He said it was interesting to observe how on the basis of this newest conception some of the very same signs which were previously considered as essential manifestations of the disease were now artificially produced for therapeutic purposes. The various attempts to influence favorably the course of infectious diseases by the artificial production of leucocytosis was another venture to utilize therapeutically one of the methods of defense and self-repair employed by the body against the cause of inflammation. Fever was another means of repair which was now being tried by various investigators as a curative agent. He referred to the experiments of Opie, in which tuberculosis of the pleura and lungs of dogs was cured or greatly mitigated by the intrapleural injection of sterile pus obtained from another animal. Learning the methods of nature should not imply that one had to follow them blindly. On the contrary, one should improve upon them. In studying self-repair, one need only to get a hint as to nature's methods; but he was a bad pupil who did not try to do better than his master. Nature strove only to avoid death; the physician had an additional duty, and that was to make life bearable. Among the new creations he mentioned the antitoxins, bacteriolysins, antiendotoxins, agglutinins, precipitins, and coagulins. The organism no doubt could reproduce other substances in its struggle against disease. Enumerated instances would suffice to prove his contention that the fact of spontaneous recovery of the organism from disease could be and had already been utilized with great profit in favor of scientific and practical therapeutics. Pathological therapeutics promised to be the most efficient method of studying therapy.

Dietetic and Hygienic Therapeutics.—Dr. David L. Edsall of Philadelphia said that there had been, during recent years, a great tendency towards what was considered heresy, gentlemen who rejoiced in the growing condemnation of drugs and the manner in which hygiene and diet were superseding the use of drugs. He had been interested during the past few years in learning just what the practitioner knew of diet and hygiene, especially the younger members of the profession, and they were frank in acknowledging that that could not get the same results from diet and hygiene that they could from the use of drugs. It was deplorable to learn how few families were instructed in the regulations of diet and the proper hygiene in cases of typhoid fever; not in 10 per cent. of the families in which he made inquiries was any suggestion as to diet and hygiene made. The use of drugs was presented to the students in a way whereby they could obtain an intelligent reason for using them. With regard to diet and hygiene it was by experience that they gathered together knowledge from many sources. In hygiene and, to a large extent in diet, it was not necessary to learn a large number of new facts, but to correlate the knowledge gained from physiology and pathology, and especially from etiology. There was in recent years such a strong interest in scientific matters that there was a tendency to overlook the commonplace, such as sex, age, occupation, etc., which could be studied with interest and profit. As a consequence of inability to correlate scientific knowledge with practical knowledge, the end result was that the use of diets and instruction in hygiene suffered. These things could be easily corrected by attention to the new knowledge. It was a very common thing to have foods administered without any conception of their food value, and this he believed to be a dangerous procedure.

Organotherapeutics.—Dr. Reid Hunt of Washington said there was an interesting group of secretions which had been called hormones, and should be studied along three lines: (1) There should be a more thorough study of the role of hormones in health and disease. (2) One should be able to obtain hormones in a suitable form for therapeutic purposes. (3) One should know more of the influence of hormones on the body itself. Much advance had been made in the knowledge of the thyroid in recent years, and very important advances had been made recently in recognizing the independent function of the parathyroids. It had also been shown that the pituitary body secretion had some effect upon urinary secretion. A very important discovery was that of secretion. Not much had been learned regarding the internal secretion of the pancreas. Advances had been made in the study of the internal secretion of the ovaries, and its influence upon the uterine muscle. Also that the secretion from the corpus luteum was necessary to effect a fixation of the embryo in the uterus. It was interesting to note that about 267 organotherapeutic products had been described in the medical journals and elsewhere. The majority had fallen into the hands of quacks who claimed to be able to cure all forms of disease. He believed that many of these products could be made synthetically and were of value. He called attention to the fact that many believed that hydrochloric acid had no action in the stomach but did have upon the mucous membrane of the dodenum, causing a stimulation of the pancreatic secretion. Iodine had a direct effect upon the thyroid, both clinically and experimentally.

He believed the activity of the thyroid ran parallel to the iodine content.

The Present Status of Serum and Vaccine Therapy.—Dr. Mark W. Richardson of Boston considered in general the antitoxins, bacteriolysins, antiendotoxins, opsonins, vaccines, filtrates, and residues. He said that one of the most important uses of fresh blood sera was in the prevention of hemorrhage. He considered briefly actinomycosis, anthrax, cancer serum, cerebrospinal meningitis (referring particularly to the work of Dr. Simon Flexner), cholera, infections due to the colon bacilli, typhoid fever, bacillary dysentery, erysipelas, exophthalmic goiter, gonorrheal infections, leprosy, leukemia, plague, pneumonia, sarcoma, antisnake venom, tetanus, tuberculosis, typhoid fever, etc.

Psychotherapeutics.—Dr. Llewellys F. Barker of Baltimore read a paper on this subject which included a brief historical résumé of the subject and a discussion of the advantages and limitations of the psychotherapeutic methods in vogue at present.

Radical Cure of Constipation by Psychotherapy.—Dr. Irving P. Lyon of Buffalo said that chronic constipation was generally looked upon and treated as a local disease of the intestine. This view was erroneous, and if strictly followed usually led to failure in treatment. Chronic constipation was generally a simple psychoneurosis—a mental habit or conviction of constipation, by which the normal innervation of the intestine was obstructed or altered. In the treatment, the psychical basis of the disordered function must be recognized, emphasized and utilized. Drugs and special local measures should be regarded as unnecessary, if not positively harmful. The patient's mentality or conviction of constipation should be changed at once, and at the first interview the patient ought to leave the doctor's office thoroughly convinced that constipation was merely a faulty habit that could be immediately overcome. With this new conviction impressed, it would be found easy to establish a new habit of regularity of function. The cure was established as a rule within a few days, often on the first day, seldom requiring more than a week or two. His personal experience with the method of treatment had been limited to the last two years in sixty-nine cases, with the following results: Complete cures, sixty-seven; partial cures, one; failures, one.

Physical Therapeutics.—Dr. R. Tait McKenzie of Philadelphia said that exercise as a therapeutic agent must include all means by which the body might be acted upon by movements active or passive, by the hand of the operator, or by a machine devised to replace it. Active exercises included games which preserved and cultivated the old coordinations of throwing, catching, striking, climbing, running, and leaping, necessary for the complete development of the individual, but difficult to get naturally under city conditions. Exercises he subdivided into those of effort and those of endurance. Under exercises of effort he included muscular action, violent, with concentration, and enormous increase of blood pressure which went down rapidly. The contraindications were arteriosclerosis and advancing age, valvular heart lesions, and active pulmonary tuberculosis. Under exercises of endurance he included easy movements, repeated till the onset of fatigue, with the blood pressure rising slowly and remaining high, pushed to the toxic dose, and fatigue fever from the accumulation of waste products. The contraindications were anemia and cachexia from any cause. In sound young men, in exercises combining both, like boat racing, no evil effects were to be found. The after-history of 'varsity crew men showed an increase of two to four years over expectation of selected lives as estimated by actuary tables of life insurance companies. Under duplicate movements he included direction of movement controlled and resistance prescribed, in other words, measuring the dose. The advantages of this were in accuracy, in specialization and isolation of muscle groups, and in stretching of contracted parts beyond voluntary power of the patient. In passive movements no will was required, and this acted on muscular nutrition mechanically. Under this was classed (*a*) massage: stroking, kneading, pinching, striking and shaking; (*b*) mechanotherapy: Zander's machines for massage and vibration. The greatest judgment and care were required to get the accurate kind and amount of exercise for the conditions to be treated. With regard to posture, faults were seen in the spine and the arch of the foot. In the spine, there were found exaggeration of the anteroposterior physiological curves, round, stoop shoulders, lateral deviations, scoliosis, always with rotation. Ninety per cent. of such cases were due to some form of fatigue. The treatment consisted in stretching the contracted parts, in the development of the normal muscle control. He emphasized the importance of isolating groups to be acted upon so as to postpone constitutional fatigue. Mechanical support was only necessary to retain the improvenment gained and to keep the original causes from acting. This was especially true in flat foot. In speaking of the heart and circulation he recalled Oertel's demonstration upon himself at the age of thirty. The possibility of climbing exercises, accompanied by limitations of fluids, and the establishment of his cure by physical training and "drying out" for heart and obesity cases were considered. The Schott brothers' treatment was by carbonated brine baths and duplicate movements. The effect of exercise was to slow and strengthen the pulse, with a reduction of dilatation. A contraindication was arteriosclerosis. In the reduction of obesity it was best undertaken up to the age of forty. Deposits of fat became localized in the pericardium, omentum, and mesentery, and daily treatment should last one month. The exercises should be trunk flexions and rotations, thigh abductions, flexions, etc., using the large muscle masses. This should be followed by hill climbing where it was possible. The diet should be regulated and organotherapy used in most cases. The contraindications were advancing age and lowered vitality. Constipation, when the result of sedentary habits, could be controlled by exercise. Horseback riding, Zander's machine, the "Camel," rotations and flexions of the trunk, massage of the abdomen following the course of the colon, were valuable. When hernia was due to atony of the abdominal muscles and a patulous abdominal ring, the cure was hastened by developing muscles which protected and closed the ring. Neuralgias and headaches were frequently controlled by exercises. In the later states of neurasthenia, rest cure massage to assist assimilation and the active exercise were beneficial. In infantile paralysis, massage would preserve nutrition and increase the circulation to the affected parts and prevent contractures, with active exercise when any power remained. He mentioned Hudson Makuen's theory of the relation of breathing and phonation to stammering, and their reeducation to coordination. In tabes dorsalis, the symptoms of ataxia were treated by exercise, to reeducate lost coordination. The work given should be very simple, such as rising and sitting down, walking forward, backward, and zigzag. Accuracy and difficulty were increased with improvement. Certain ingenious devices had been described by Frankel. The dangers of treatment depended on the constant loss of sensibility to fatigue and profound exhaustion, rapid feeble pulse, mental worry from repeated failures, etc. This should be looked for, and treatment should last only two or three minutes at first. There was usually a marked improvement in the ataxia, and this was usually retained for years. In summarizing he said that exercise in its application to pathological conditions of posture, circulation, nutrition and the nervous system, must depend for success on the accuracy of the dose, and persistency in following out the course of treatment, and careful observation during the progress of such a course.

Dr. Hobart A. Hare of Philadelphia thought that the most important thing that had been impressed upon the members of the Association and those in active practice was that there was still a wide breach between experimental pharmacology and bedside experience. A large amount of success in practice depended upon empiricism rather than upon a knowledge of the pharmacological action of remedies. He asked his hearers not to decry pharmacological research. One could not throw aside measures that had been used for years and with success, measures that had triumphed in past years. One thing had impressed itself forcibly upon him, one of the points that Dr. Meltzer had brought out, the extraordinary ability of the body to adjust itself to the onslaughts of disease. Dr. Hare said he was confident that many of the procedures used by our ancestors, but now given up, were based on good reasons, as, for example, the method used for the production of sweating in the early stages of acute infections and other conditions. Now we were in the habit of using drugs, like pilocarpine, which, in the hands of the skilful physician, would produce results beneficial and admirable. It was now taught that certain drugs did good by stimulating the heart muscle; that others like atropine did good by acting on the vasomotor system in conditions of shock, etc.; this was very crude and did not represent the true physiological action of the drugs at all. Veratrum viride was recommended in puerperal eclampsia, and far and wide physicians had claimed for it extraordinarily good results. Dr. Hare had never used it in this condition and did not know how it acted in such conditions. Psychotherapy was valuable, but should be used in conjunction with other measures. He closed by urging more pharmacological research and investigation, and not to give up the old methods until the newer remedies worthy of displacing the older ones had been found.

Election of Officers.—*President,* Dr. Victor C. Vaughan; *Vice-President,* Dr. Henry Hun of Albany; *Secretary,* Dr. Geo. M. Kober of Washington; *Recorder,* Dr. S. Solis Cohen of Philadelphia; *Treasurer,* Dr. J. P. Crozer Griffith of Philadelphia; *Councillor,* Dr. S. J. Meltzer of New York; *Representative on the Committee on Congress of American Physicians and Surgeons,* Dr. F. H. Williams; *Alternate,* Dr. W. S. Thayer.

The Clinical Value of the Tests of von Pirquet and Calmette.—Drs. Chas. L. Greene and Frank E. Burch of St. Paul presented this paper with the following summary: (*a*) The reaction was comparable and practically parallel to the old injections tests, inasmuch as the percentage of reactions closely approximated that obtained by Beck and others using the older method. (*b*) The two tests ran more nearly parallel than the reports of Wolff Eisner and others indicated. (*c*) The v. Pirquet was the more reliable and less subject to accidental error through fortuitous irritation. (*d*) Both active and arrested tuberculosis reacted to the tests. (*e*) The more vigorous reactions seemed to indicate greater individual resisting power and had a certain prognostic value. (*f*) The low reaction was more common in arrested tuberculosis. (*g*) The advanced cases with low resisting power afforded a slight reaction or none at all. Some showed a transient slight reaction reported by Wolff Eisner. (*h*) The positive reactions in the general clinical cases were so numerous as often to be merely suggestive and retrospective. (*i*) The negative value was extremely great and of high clinical utility. (*j*) The method of v. Pirquet seemed to be free from danger, but a sufficient number of bad results from the conjunctiva test had been reported to justify caution in its use. (*k*) The absence of local reaction signs, such as occurred in the old tuberculin tests, was more than compensated for by the lesser risk involved. (*l*) Relatively few cases reacted which did not show reasonably good evidences of past lung involvement, especially apex retraction as determined by Krönig's method. (*m*) The test was well worthy of, and adaptable to general use, but only with the full knowledge and appreciation of the other limitations.

A Comparison of the von Pirquet, Calmette and Moro Tuberculin Tests and Their Diagnostic Value.—Drs. S. McC. Hamill, Howard C. Carpenter, and Thomas A. Cope of Philadelphia presented this communication. The paper contained a brief review of the technique pursued in the carrying out of the various tests, a description of the class of cases in which they had been used, the results as applied to each class, and other matters, the gist of which was presented to the Association at its last meeting, and which had appeared in the report of that meeting in the Medical Record.

Tronchin: A Sketch of His Life.—Dr. F. C. Shattuck of Boston said that Tronchin was a great practitioner, who wrote an enormous number of letters and but one thesis, on "Colica Pictonum." He was born in Geneva of first-rate stock, and received the best education that Geneva afforded. Once, when in London, where he met Richard Mead and asked him to what he attributed his success, Mead replied: "I have perhaps not done much good, but I have tried not to do harm." This speech influenced Tronchin's future. He studied medicine for three years and then settled in Amsterdam, where he was twenty years in general practice. He was called to Paris to inoculate the children of the Duke of Orleans for smallpox. He then went to Geneva, where people from all over Europe flocked to him. In 1763 he returned to Paris for good, becoming the physician to the Duke of Orleans. He died in Paris. His claim for immortality was that he was a true follower of Hippocrates, and was one of the greatest practitioners the world ever saw.

Fatigue in School Children as Tested by the Ergograph.—Dr. Rowland G. Freeman of New York gave a description of the different forms of the ergograph which had been used, and reviewed the previous work with the ergograph to test fatigue. The Crampton test, he said, was of no value in children. The Story ergograph was of no value, because the accessory muscles were used. In his testing of the children of the New York public schools he found no such amount of fatigue as Christian found in the children in the Chicago schools.

Ascitic Exudate in Typhoid Fever.—Dr. Alexander McPhedran of Toronto reported four cases of typhoid fever in which well-marked signs of peritoneal effusion were present for about two weeks, disappearing in convalescence. There were no other indications of peritonitis.

Further Observations on Pleural Reflexes.—Drs. Joseph A. Capps and D. D. Lewis of Chicago said they had made a comparative study of the effect on blood pressure of irritating with various antiseptics the pleural cavity of healthy dogs and dogs with pleurisy. They also offered the results of a series of experiments to determine the effect on blood pressure of various irritants applied to the parietal pleura. Fifty cm. of the fluid used was injected; then the irritating fluid was washed out soon after with water. In the case of peroxide of hydrogen, great care was used to get rid of any gas. The dogs with pleurisy were really empyema dogs. The following table was presented, showing the results of their experiments:

Irritating fluid.	Condition of dogs.	Number of experiments.	Fall in blood pressure.	Falls per cent.
Hot water	Normal	8	0	0
Hot water	Pleurisy	5	0	0
Cold water	Normal	4	1	25
Cold water	Pleurisy	4	2	50
Formaline and glycerine	Normal	11	4	36
	Pleurisy	11	6	56
Iodine solution one per cent.	Normal	6	1	16
	Pleurisy	9	2	22
Peroxide of hydrogen	Normal	9	1	11
	Pleurisy	11	6	55

Acute Pancreatitis.—Dr. Joseph Sailer of Philadelphia read this paper. Pancreatitis was produced by the injections of oil into the duct of Wirsung. There was great rapidity of the process as well as completeness and

there was apparent absence of any specific toxic substance produced in the pancreas itself. An experimental pancreatitis might run a typical course without any bacterial infection. Certain ferments, particularly the fat-splitting ferments, might escape from the pancreas and digest suitable tissues in the vicinity of the pancreas. With regard to the views on pancreatitis it had been claimed by some that it was bacterial in nature; by others that it was due to the escape and activity of trypsin; again many believed that they were not in a position to make any definite statement.

Some Clinical Features of Pancreatitis.—Dr. JOHN H. MUSSER of Philadelphia gave some interesting results of the studies of nine cases of acute pancreatitis. In one case an early expression of carcinoma of the pancreas might be seen in an attack of acute pancreatitis. This patient was fifty-six years old, and he had definite symptoms of acute pancreatitis. These acute symptoms subsided at the end of three or four weeks and then the phenomena of carcinoma of the pancreas first arose. The primary focus was in the breast. In another case an acute pancreatitis with the occurrence of hemorrhage caused sudden death in the course of typhoid fever. The autopsy in this case showed a severe hemorrhage from the pancreas. In another case there were symptoms of a renal calculus occurring at the same time with symptoms of acute pancreatitis. Notwithstanding the complication and the disagreeable features in this case they had the temerity to advise operation. They found quite a large collection of fluid in the layers of the omental cavity hemorrhagic in nature. This was the first case ever diagnosticated in Philadelphia. The patient died of peritonitis. Patients might recover from acute pancreatitis. The diagnosis of pancreatitis must be based upon the previous history, the acute symptoms, the symptoms of inflammation behind the stomach, and by the abdominal symptoms, with which all were familiar. In two of the nine cases, the patients were treated for diarrhea. An acute anemia was characteristic in five out of the nine cases. A subnormal temperature occurred in five cases, occurring in from one to five days after the onset of the disease. Then a gradual rise took place. Dyspnea occurred in eight out of the nine. There was an increased pulse rate in all the cases. The Cambridge test was positive in all the cases.

Dr. S. J. MELTZER of New York called attention to the findings at the autopsy of the late von Bergmann. The diagnosis prior to his death was a kink of the colon producing peritonitis, but the autopsy findings showed that in all probability he died of an acute pancreatitis.

Hypernephroma of the Kidney, with Metastasis to the Sternum, Simulating Aneurysm of the Aorta.—Dr. AUGUSTUS A. ESHNER of Philadelphia said that hypernephroma was a tumor of adrenal structure, involving the adrenal gland itself, or situated in some other organ or tissue. It might be small and benign and remain encapsulated, or large and malignant and give rise to metastasis. The primary growth was often situated in the kidney, while secondary growths had been observed in many structures, and especially in the bones. The symptoms did not differ essentially from those of other forms of neoplasm. In the case reported by Dr. Eshner a pulsatile elastic tumor of the manubrium sterni, in the course of the aorta, and yielding a systolic murmur on auscultation, was found after death to be a metastatic growth secondary to a hypernephroma of the kidney.

The Importance of the Consideration of Negative Results in Blood Cultures.—Dr. E. LIBMAN of New York said that in all the culture work up to this present time stress had been laid upon the positive findings. As the result of a study of a large number of blood cultures the writer had found that the absence of bacteria was very often significant in giving diagnostic and therapeutic indications. Negative blood cultures were important in the diagnosis of endocarditis and abdominal disease.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending August 1, 1908:

	Cases	Deaths
Tuberculosis Pulmonalis	461	154
Diphtheria	187	17
Measles	153	11
Scarlet Fever	123	4
Smallpox	—	—
Varicella	14	—
Typhoid Fever	76	13
Whooping Cough	29	4
Cerebrospinal Meningitis	12	11
Malarial Fever	—	—
Totals	1055	214

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, for the week ending July 31, 1908:

SMALLPOX—UNITED STATES.

		Cases.	Deaths.
Illinois, Chicago	July 11–18	1	..
Indiana, Fort Wayne	June 27–July 4	1	..
Indianapolis	July 12–19	17	..
Lafayette	July 13–20	1	..
South Bend	July 11–18	4	..
Kansas, Wichita	July 11–18	1	..
Louisiana, New Orleans	July 11–18	1	..
Ohio, Cincinnati	July 10–17	1	..

THE SURGICAL TREATMENT OF EMPYEMA.

BY P. T. O'CONNOR, M.D.,

WATERBURY, CONN.

SURGEON TO ST. MARY'S HOSPITAL.

SURGICAL procedure, if not based upon thoroughly scientific principles, will not bear the analysis of time. Method, technique, and certain other factors may change, but the principles upon which those rest, if rational and effective, always remain the same. The struggle of the ages in medicine, as in other departments of science, has been the emancipation of truth from authority. Therefore, in order to discuss intelligently the subject under consideration, we must appeal to a law that existed before the ordinances of man—we mean, the law of eternal truth.

The surgical treatment of empyema dates back to the time of Hippocrates. We have read of the Alexandrian merchant, who was suffering from an accumulation of fluid in the pleural cavity, with signs and symptoms indicative of an aggravated form of compression of the lung. He had submitted to all manner and form of internal and external medication. The holy incantations of Egypt were recited in his behalf, and even the sacred Apis bull was printed upon his chest, all without relief. This suggests the thought of seeing the afflicted individual standing before the ancient sphinx of Oedipus, listening to the voice of Memnon floating over the twilight of the Nile—a voice which seemed to whisper in his ear: "To Hippocrates for relief. The mere despair of surgery he cures." Subsequent events proved that he must have heeded the voice, for later on he knelt at the feet of Hippocrates for treatment. The master mind of this great genius, after a careful physical examination, made a diagnosis of empyema. Operative measures were advised and accepted. The plan of procedure followed was: Free incision down to the ribs, trephining the latter, incision of the pleura, and evacuation of pus. Hippocrates, by this operation, led his disciples from the borderland which separates the visible from the invisible, the palpable from the impalpable, drew aside the veil of Isis, and demonstrated to them and the profession that there was one, and only one rational and effective plan of treatment for empyema; that was, incision, trephining the rib, incision of the pleura with knife or actual cautery, gradually allowing the pus to escape, thus giving nature an opportunity to re-establish her normal condition. Down through the ages, up to the time of Lister, we find no improvement in the operation as performed by Hippocrates.

Paget, in his work, "Surgery of the Chest" (1897), says: "If we look again at history, we find whole ages of neglect or perversion of the truth and it is impossible to understand how this Hippocratic treatment of empyema became so hopelessly lost, when we find the description of it in the works of Hippocrates himself. If it be true that Galen invented the aspirating syringe, this was probably the beginning of the evil; the Hippocratic operation fell into disrepute, and there was no method to take its place; incision, either with the knife or actual cautery, was almost wholly abandoned, save by some of the Arabian physicians. By the time of the Renaissance, with return to Greek art and literature, it was too late to go back to Hippocrates. Surgery had become embarrassed by the bad results of septic wounds, and it was held as dangerous to let air into the pleura as to leave an effusion unrelieved, nor was the difference between serous effusion and purulent effusion properly understood or recognized. Thus it happened that our art drifted, in spite of Ambroise Paré and Guy de Chauliac, into that disastrous period when empyema was treated by simple puncture; and not even Laënnec could save it. The doctrine that puncture for serous effusion would convert it into a purulent effusion, and that the entry of a few air-bubbles into the pleura might set up a fulminating suppuration, blocked the way; and blocked it still might be, but for Lister.

The history of the treatment of empyema, from Hippocrates to Lister, would justify a revival of the oath of Hippocrates, "In purity will I practise my art," if it were understood that the purity must be not only a clean life, but also a method of operation. For example, as late as 1872, M. Bouchut published, as an instance of good, profitable surgery, a case of empyema in a boy, age nine, cured in 16 months after 58 punctures. In another case, he punctured the chest in 11 months, 123 times. Lilly records a case in which he made 56 punctures. Gimbert, in a child 11 years old, made 74 punctures in nine months, obtaining a grand total of 30 pints of pus. And the worst of it all is, out of 48 patients thus tormented, only six were saved. Nor did freer incision, before Lister, fare much better. Out of 12 patients under the care of Velpeau, not one recovered; out of 58 under the care of Dupuytren, all but two died; and Sir Astley Cooper complained that he could never get a single cure. There are three series of cases, less than 25 years ago, whose lives might have been saved if they had been under the care of Hippocrates. The old routine treatment by repeated puncture or aspiration has, happily, gone forever.

In the early sixties of the past century, or, more correctly speaking about 1868-1870, Lister, after a life's work of careful preparation and research, partly based upon the experimental work and researches of Pasteur, advocated the principles and practice of antiseptic surgery. With the introduction of this wonderful epoch-making achievement

*Read before the New Haven County Medical Association, April 23, 1908.

of Lister, surgery was taken out of the field of empiricism, away from medicine, and placed upon a firm and lasting foundation. Medicine has had more centuries of evolution than has surgery. We can trace it back to the beginning of the Christian era; back to the time of Hippocrates; beyond the

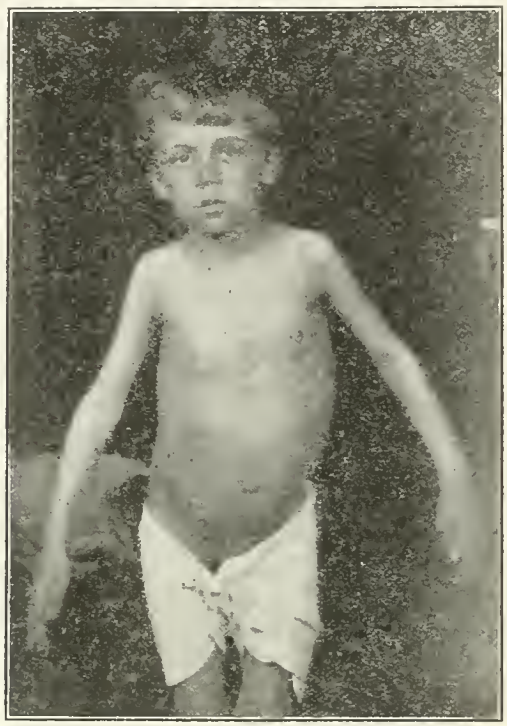

Fig. 1.—Showing extreme prominence of the left side of the chest, with bulging of the intracostal spaces, indicating accumulation of fluid in this, the sound side. Note secession of the ribs on the right, the affected side, suggestive of no accumulation of fluid—a condition exactly the reverse of the usual order or of what might be expected.

time of Hippocrates until it is lost in the twilight of fable. The opsonic index seems to be a step in the right direction. With further development it may, at least we hope so, do for medicine what Listerianism has done for surgery, place it upon a more thorough and scientific basis. Subsequently, bacteriology had become established as an essential department in medicine, and soon began to cast the rays of its powerful searchlight in certain directions and to illuminate the valleys of darkness. This, in turn, paved the way for asepsis which supplanted antisepsis. Up to the time, and immediately following the latter event, American surgeons had not received the proper attention that the character and importance of their work deserved. From the date of the first edition (1888) the standard classic of Jacobson's "Operations of Surgery," conceded the best general treatise on surgical operations in the English language, no other writer has done more to bring home to operating surgeons how much can be gained by their turning their eyes to the advances made by Trans-Atlantic surgeons, as well as by those on the continent of Europe. In other words before the advent of this book, the prestige of the surgeons of America had had scant justice in comparison with that of the surgeons of Germany and France. In 1889, within a space of twenty years since the establishment of antiseptic surgery, Prof. Arpad G. Gerster brought forward his epoch-making work on "The Principles and Practice of Antiseptic and Aseptic Surgery." He taught us that if we were aseptic in our work, there was little, if any, need of antiseptic, unless it be in an area already infected.

The aseptic teaching of Gerster was evolved from the antiseptic doctrine of Lister. Following the introduction of aseptic principles and practice came a complete revolution in surgery and surgical technique, so that to-day there is scarcely an organ or tissue of the body that cannot be manipulated with a fair degree of impunity. At the time asepsis was established as an essential department of modern surgery, America had to contend with England, France and Germany in the lead. While the latter country was concentrating her energy, strength and application upon the minutiæ, she seemed to have lost sight of the perspective. Finally the rare intellect of the Mayos began to assert itself, those trained minds, with generations of culture back of them, working side by side, progressing step by step—not by leaps and bounds. They (of course with others) have placed American surgery upon a higher plane of thought, reason and action, until to-day she stands alone amid the nations of the earth, like Pompey's column at Alexandria, towering above them all.

Under the old order of things, the practical value of a surgical procedure was notoriously based upon erroneous premises, namely: What is your mortality? This will no longer stand the test of modern times, with the rapid advancement of surgery and technic. The surgeon obviously assumes great responsibility and is confronted with three important factors; (a) mortality, (b) disability, (c) permanency of cure. Those are the conditions upon which will rest the triumphs of future progress. The mutilating operations of Estlander and Schule have served their purpose and are now of historical interest only. They are a reflection upon both med-

Fig. 2.—Showing the pronounced lateral curvature of the spinal column which might be mistaken for tuberculous caries of the dorsal vertebræ. The curve was even more pronounced than is shown in the picture.

icine and surgery. The former failed to make a diagnosis during the acute and curable stage. The latter disabled and disfigured the patient, with a high mortality, too often with no permanency of cure.

The physician who fails or neglects to make a

positive diagnosis of empyema during the acute and curable stage, commits a crime almost approaching criminal negligence. Should the refinements of physical examination leave him in doubt, he has at his disposal the aspirating needle, which can be used with aseptic precautions and will clear up the situation at once. When the existence of fluid is diagnosed or suspected, by exploratory puncture its presence and character are determined. We are in accord with Kocher ("Operative Surgery", 1903) who, in quoting Broca, says: "Broca is right in saying that empyema necessitatis should never be allowed to develop. A purulent pleural exudate cannot be too early evacuated, for it is only in the recent empyemata that there is a prospect of the lung fully expanding again. Physicians do not yet sufficiently appreciate that this complete mobility and expansion of the lungs is obtained by early thorough operation." Kocher also mentions Beck of New York who has published statistics which prove the value of early operation, including resection of rib. Of 110 uncomplicated cases under his observation, when the diagnosis was made early, all recovered.

Fig. 3.—Showing the normal contour of the chest, right and left sides, after the operation.

Pulmonary Decortication. George R. Fowler (*Medical News*, June 15, 1901; American Year Book of Medicine and Surgery, 1902) performed this operation in 1893 with very gratifying results. He writes: "An elliptical shaped incision was made to include the orifice of the sinus, the soft parts cleared, and about 3 1-2 inches of the fifth and sixth ribs removed. Commencing at the site of the opening of the chest wall, the pleura was isolated in the direction of the diaphragm until the latter was reached. It was then peeled off the latter until its limit towards the medium line was reached, where it was found to rest against the displaced pericardium, from which, after much difficulty, it was finally detached. This dissection was greatly impeded by the movements of the diaphragm as well as those of the heart. The dissection was completed by lifting the mass and finally detaching it from the lung above. Considerable expansion of the lung followed at once, and in the course of 28 days this was so far complete that the normal vesicular murmur was present to the level of the seventh rib. Save for a slight sinking of the chest wall at the site of the resection of the ribs there is nothing to suggest the previous existence of empyema." Fowler's original paper was published in the Medical Record, December 30, 1893.

Delorme, in 1894, performed an operation very similar to that of Fowler (American Year Book of Medicine and Surgery, 1902), and did it successfully under cocainization. Out of 29 cases of decortication by the Fowler method, the functional results were 11 cured, 6 improved, 9 unimproved, 3 died. As regards the cure of the empyema, 17 were cured, 9 unimproved, 3 died. (Delorme's original paper appeared in the Gazette des Hôpiteaux, 1894, No. 11.) Delorme has devised a method of temporary resection of the chest wall; this being done, he decorticates the lung, cleans the empyema cavity, and replaces the flap of

Fig. 4.—Showing the perpendicular line of the spinal column, restored to its normal condition after the operation.

the chest wall, providing, of course, for drainage. This operation has not found much favor. To these must be added one by Dr. Joseph Ransohoff of Cincinnati, in the *Annals of Surgery*, April, 1906, which is simply a modification of the Fowler-Delorme method. This he calls "Discission of the Pulmonary Pleura." It consists of "gridironing" the pulmonary pleura with many parallel incisions, removed from each other about a quarter of an inch, and crossing these obliquely, or at right angles, with other parallel cuts.

All these methods are indicated in chronic empyemas, where operation has been delayed, and in cases where the lung fails to expand after adequate drainage of the pleural sac, subsequent to primary operation. They are based upon the idea that when the lung has once completely collapsed and become firmly fixed the pulmonary pleura has lost its expansibility, owing to inflammatory thickening, so that it will not allow sufficient amount of re-expansion to permit the pulmonary and parietal surfaces to come into contact. Lloyd, whose name is well associated with surgery of the chest, especially that of empyema, in a very instructive article in *Annals of Surgery*, March, 1907, says: "It is now over fif-

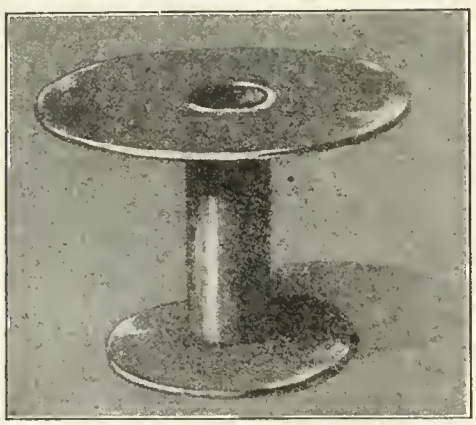

Fig. 5.—Double-flanged empyema tube. This is simply a piece of rubber tubing with a flat piece of rubber on either end. The smaller flange rests against the inner surface of the chest wall, while the larger flange rests upon the skin and prevents the tube from slipping into the pleural cavity.

teen years since I began to experiment on these cases in order to determine if there was not some way to bring about this complete expansion of the lung without extensive and mutilating operations upon the chest wall. In 1893-4, respectively, when Fowler and Delorme suggested their method, I discontinued experimental work for a short time and adopted their method of decortication. It was not long, however, before I was convinced that the difficulties attending the freeing of the lung from its pleural covering were so great, and the result following the attempt was so often unsatisfactory that I took up again this experimental work." We have been informed by an able colleague who had operated on a case of chronic empyema and insisted at the time of operation there was secondary rib formation, the result of the chronic process; subsequently the patient was sent to one of the New York hospitals, and the attending surgeon was informed of the findings at the first operation, but the latter laughed in derision at such unique condition of things. Later, however, the New York surgeon operated on the patient, and informed *our* colleague that the latter was right in his diagnosis; there was a secondary rib formation. In this, however, we cannot concur, and do not believe that such was exactly the condition found to exist at either operation. While at the Mayo Clinic in connection with St. Mary's Hospital, Rochester, Minn., June to September, 1907, it was our privilege to observe Dr. Charles H. Mayo operate upon a chronic case of empyema of long standing. In the region of the right nipple there was a chronic discharging sinus. This case necessitated a most radical operation, consequently the anterior lateral incision was made which exposed the entire right chest cavity. No normal lung was found to exist. The remnant of a once normal lung, reduced to a ribbon-like mass running parallel with the spinal column, and attached firmly from apex to diaphragm, in such a way that had it contained any vitality, expansion was practically impossible. The pleura was very much thickened and, in certain places, folded upon itself in such a manner as, owing to calcareous deposits (calcification), gave the appearance of secondary rib formation. The pleura, with the ribs, were thoroughly resected, and the flap replaced. Lloyd has recently advocated a method of primary operation by which he believes that the permanently collapsed and cirrhotic condition of the lung can be avoided. He makes a sufficiently large opening into the chest to enable him to introduce one or more fingers, or the entire hand into the pleural cavity. After the pus has been drained away the anaesthetic is suspended and the entire lung separated from the chest wall by breaking down all adhesions. This manipulation causes the patient to cough violently, which by increasing the intra-tracheal pressure causes an immediate expansion of the lung. He reports over 200 cases treated by this method with a mortality of about 20 per cent.

Thoracotomy, with resection of a rib, according to Brewer (Keen's "Surgery", Vol. III.) is the operation of choice in all cases where drainage of the pleural cavity is required. The extra time consumed in the resection of the ribs is not more than two minutes, and most surgeons now adopt this procedure in preference to simple thoracotomy. The site of operation and the position of the patient are the same as in thoracotomy. The operation can be performed with local anesthesia, but in children and in nervous individuals general anesthesia is to be preferred. A cutaneous incision, four or five c.m. in length, is made directly over the rib to be resected. The tissues, including the periosteum, are divided to the bone, the periosteum is then stripped from the bone by a raspatory or periosteal elevator both in front and behind, care being taken in removing the membrane from the groove on the inferior border of the rib to avoid wounding the intercostal vessels and nerves. As soon as the bone is freed from its periosteum, a segment of the rib, three or four c.m. in length, is removed with bone forceps or the Gigli saw. When the bleeding has been arrested the cavity is opened by an incision through the periosteum, internal intercostal aponeurosis, and parietal layers of the pleura. One or more drainage tubes should then be introduced, or the Wilson's double-flanged tube. It is sometimes necessary to excise more than one rib to allow digital exploration of the thoracic cavity or other intrapleural manipulation. This can generally be accomplished through one incision, made somewhat longer to allow greater retraction of the soft parts. Each rib should be exposed and resected subperiosteally in the same manner as indicated above.

Byrant, in a recent article (Jacobi "Festschrift") has advocated aspiration drainage of the chest in empyema by means of a collapsible rubber bulb,

which he attaches to the outer extremity of a drainage tube. The latter should reach to the bottom of the suppurating cavity, and should accurately fit the opening in the chest wall, and near its attachment to the bulb should be fitted with a stopcock, which permits the removal and emptying of the bulb without admitting air to the chest. The tube and the bulb are strapped to the chest wall and covered by the usual dressings and binder. In case of acute empyema, the Mayos in their clinic use the double-flanged drainage tube (Fig. V.) which they consider simple, practicable and efficient. This is simply a piece of rubber tubing with a flat piece of rubber on either end, made in different lengths to fit different thicknesses of chest wall. In appearance it is very similar to a spool. The smaller flange of this tube rests against the inner wall of the chest, while the outer and larger flange rests against the skin and prevents the drainage tube from falling into the pleural cavity.

The writer, while at Ochsner's clinic, in connection with the Augustana Hospital, Chicago, September to October, 1907, has observed that he is a great advocate of, and practises through-and-through drainage. After making the usual rib resection, the pleura is penetrated and a counter opening may seem desirable. To make this, pass a forceps through the wound, through the cavity, and with its point elevate the tissues at the position selected. Cut down on the forceps, and push them through the new wound. Grasp the perforated rubber tube in the jaws of the forceps and pull the tube through the cavity. Sometimes two tubes are used in the same manner. We then have established efficient through and through drainage. If at any time it is desired to withdraw the tube and introduce another, fasten a stout thread to the end of it, and in withdrawing the tube pull the thread through the cavity: with this thread in situ, it is easy to introduce another tube. Later the tube may be displaced by a few strands of silkworm gut. Tubular drainage must be kept up until all the discharge has ceased.

The case we present here, with illustrations, being out of the usual order of things: presenting conditions directly the reverse of what might be expected, may perhaps be worthy of further consideration, as showing what can be accomplished, even in an aggravated form of empyema, by prompt diagnosis and early thorough surgical operation.

Herbert R., aged 8 years, was taken ill with pneumonia March 6 to March 14, 1907, inclusive, from which he made an uneventful recovery. Five weeks later his mother observed that the boy walked lame and that it was impossible for him to stand erect. The case was in the service of Dr. B. A. O'Hara, who kindly asked the writer in consultation. After a careful physical examination, we arrived at a diagnosis of empyema, which, of course, was corroborated by the aspirating needle drawing off about an ounce of pus. A specimen of the latter was sent to the pathologist of the Waterbury Hospital, Dr. Charles Engelke, for bacteriological examination, who reported as follows: "Examination of pus from empyema thoracis. Fluid found to be free from microorganisms. Cultures made in broth and on serum gelatin and agar media. After three days, no signs of growth of organisms."

Operation was advised, which was at first refused by the family, but after a few days of further deliberation they finally consented. Consequently, five days later, April 27, 1907, about three inches of the seventh rib, in the region of the posterior axillary line was resected subperiosteally. The pleura was then incised and an enormous quantity of pus gradually allowed to escape. The lung was compressed against the spinal column, adherent from apex to diaphragm. The adhesions were thoroughly broken up by digital manipulation and with a curved periosteotome, and immediate expansion of the lung followed. Large masses of coagulated lymph were scraped away, using a spoon as a curette. The excess of coagulated lymph that was set free during the course of manipulation was washed out of the pleural cavity by pouring hot saline solution into the wound from a pitcher. In this way there is no increase in hydrostatic pressure, and the fluid poured in is washed around by the expanding lung and flows out again through the free opening at each expansion. As soon as the lung had fairly well expanded, two drainage tubes were inserted, the skin closed around the tubes, and a liberal dressing applied.

In conclusion we find that simple incision lacks the fundamental principles of surgery, and most advanced modern surgeons do not consider it a recognized method of procedure for the surgical treatment of empyema. The established plan of procedure, which has withstood the test of time, is that laid down by Hippocrates, with one exception. Hippocrates trephined the rib to avoid injury of the intercostal vessels and nerves, while we, with a more perfect knowledge of anatomy, prefer to resect a portion of one or more ribs, thus enabling the surgeon to introduce one or more fingers, or the whole hand, into the pleural cavity, and by intrapleural manipulation break up all adhesions, remove the large masses of coagulated lymph, and thereby accomplish a more thorough surgical operation.

TREATMENT OF NEGLIGENT SPEECH BY THE GENERAL PRACTITIONER.*

By E. W. SCRIPTURE, PH.D., M.D.,

NEW YORK.

AUTHOR OF "RESEARCHES IN EXPERIMENTAL PHONETICS, CARNEGIE INSTITUTION, WASHINGTON, D. C."; "ELEMENTS OF EXPERIMENTAL PHONETICS, YALE UNIVERSITY BICENTENNIAL PUBLICATION" "VISITING PHYSICIAN FOR SPEECH DEFECTS TO RANDALL'S ISLAND; ATTENDING PHYSICIAN TO THE N. Y. NEUROLOGICAL HOSPITAL. FORMERLY DIRECTOR OF THE PSYCHOLOGICAL LABORATORY OF YALE UNIVERSITY; LECTURER ON PHONETICS IN THE UNIVERSITY OF MARBURG, GERMANY.

THE mechanism of speech includes (1) the organs for producing spoken sounds, (2) the ear, (3) the nervous and mental mechanism of control.

These organs may all be in such a condition that they can act normally and can produce correct sounds, and yet they may fail to do so because some part of the mechanism of control does not act with precision. This results in what may be called "negligent speech." I shall now pass briefly in review some of the most common defects of negligent speech and shall describe methods of cure that can be used by every practitioner. These defects are different from those that characterize hyperphonia (stuttering and stammering), which I have discussed in a previous publication.†

FIG. 1.

FIG. 2.

*Read before the Medical Society of the County of New York, May 23, 1908.

†Treatment of Hyperphonia, MEDICAL RECORD, March 21, 1908.

Lip Defects.

Some persons use "v" for "w." For "v" the lower lip should be against the upper teeth (Fig. 1); for "w" the two lips are brought near each other (Fig. 2). To correct the fault, tell the patient to say "well, word, wind," etc.; just as he starts to say "v," press his lower lip down with your finger or a stick; he will be forced to say "w" instead.

Tongue Defects.

The most common are:

1. *"s-t" lisping.*—The patient says "toap" for "soap," "tun" for "sun," etc. The defect is quite frequent among normal children; I have had a number of them in my Speech Clinic on Randall's Island. In saying "s" the tip of the tongue is brought against the palate (Fig. 3), but a small channel is

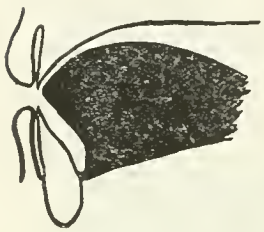

Fig. 3.

Fig. 4.

left in the middle so that a jet of air is blown through. The patient merely presses his tongue a little too hard, so that it closes the channel; this is the position that produces a "t" (Fig. 4). The cure consists in inserting a probe just over the middle of the tongue and pressing it down as the person tries to say "t"; this makes a small channel and he is thus forced to say "s."

2. *"th-t" and "th-d" lisping.*—Still more common are the children who say "tin, tree, tumb" for "thin, three, thumb," and "dis, dick, dee" for "this, thick, the." For both the sounds of "th" the tongue must be put so lightly against the palate that air escapes at the sides. The defect arises from pressing the tongue too tightly; this makes a "t" or a "d" just as in the previous case. The cure consists in inserting a probe or a stick at the side of the mouth above the tongue. When the patient tries to say "t," his tongue is pressed down at the side and he is forced to say "th."

3. *"s-th" lisping.*—"People thay I lithp but I don't pertheive it," remarked one young man. The tongue does not rise sufficiently at the edges in front to cut off the air at the sides while leaving a small channel in the middle. Tongue-tied people usually lisp in this way because they must make an excessive effort to press the tongue. Such people are cured by inserting the probe to make a well defined channel as in the s-t lisping (No. 1 above).

The frenum should be cut, if too short. This is, according to my experience, the only defect that arises from "tongue-tie." There is an antiquated belief that it causes stuttering. Among the hundreds of stutterers that pass through my hands at the Speech Clinic in the Vanderbilt Clinic, I have never seen one that was tongue-tied.

4. *"t-th" lisping.*—The patient says "wather" instead of "water," that is, he fails to close the tongue tightly across at the front. Ordinarily it is sufficient to explain to him that there are two classes of sounds called "occlusives" and "fricatives." For the occlusives the current of air passing through the mouth must be cut off at some point; for the occlusive "t" the tip of the tongue must close firmly against the palate. When it does not do so firmly, it produces the fricative sound "th."

5. *"r" defects.*—The usual one is the use of "w" for "r." The cure consists in getting the tongue in the right place for "r." One method is to teach the "rolled r," which is the regular "r" in French, German, and Italian. When the person cannot get the tongue right for this, it is useful to use another sound that requires the point of the tongue against the palate. For example, he is told to repeat "sun, run, sun, run," etc., or "tun, run, tun, run," etc.

6. *Various substitutions.*—"t" for "k." The child says, for example, "tandy" for "kandy" while he says "car" correctly. That is, although he is able to make th sound of "k" he replaces it by "t" in some words through pure negligence. Both "t" and "k" are occlusives, that is, the current of air is shut off entirely during the sound; for "k" this is done by the back of the tongue (Fig. 5). While

Fig. 5.

for "t" it is done by the front (Fig. 4). The cure consists in having the patient repeat the "k" sound before various vowels and gradually pass over to the incorrect words, *e.g.* "kah, kah, kah, ka-ka-kan, ka-ka-ka-kandy."

Velum Defects.

For most sounds the velum must be raised so as to cut off the nasal passage from the mouth. When this is not done, the sound is changed to a nasal; thus "b" is changed to the corresponding nasal "m," "t" to "n," etc. In mild cases I use a nasal indicator which shows when air issues from the nose.

There are two convenient forms of this breath indicator which anyone can make. The one shown (Fig. 6) consists of a thistle funnel over the top

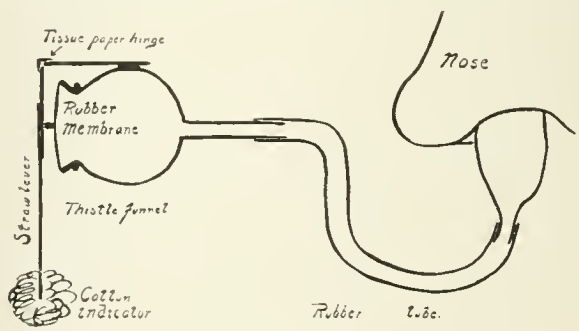

Fig. 6.—Breath Indicator.

of which a rubber finger cap is placed. A strip of visiting card is cut across and joined with tissue paper to make a hinge. A piece of wax holds one piece of the card to the funnel while the other one hangs in front of the rubber membrane. A drop of paste connects the hanging piece to the membrane. A light straw is fastened to the hanging piece and a bit of cotton is added at the bottom. The funnel is connected by a rubber tube to a nasal tip. When any air issues from the nose, it goes

into the funnel and moves the rubber membrane; the movement is indicated by the cotton.

Another form of indicator is shown in Fig. 7. The rubber tube from the nasal tip ends in a straight glass tube whose end just touches the flame

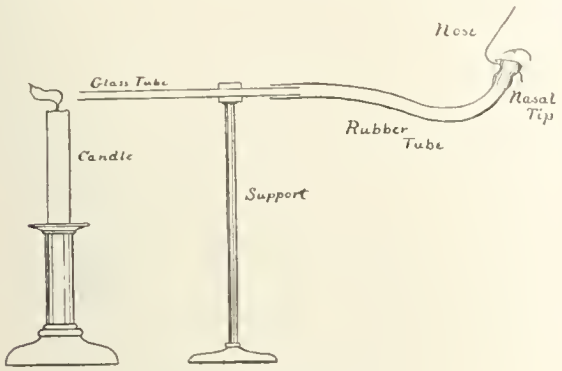

Fig. 7.—Breath Indicator.

of a candle. When the air rushes from the nose, the flame flickers.

The patient must learn to say "p, b, t, d, . . ., a, o, . . ." without moving the indicator.

In cases where the velar action is very defective, as after operations for cleft palate, I tell the patient to do things that oblige him to keep the nasal passage closed, *e.g.*, to play a mouth-harmonica, or the like. This idea I got from a little boy who found it possible to play on his harmonica by holding his nose with his fingrs.

Laryngeal Defects.

1. *Laxness of the vocal cords.*—This trouble shows itself in breathiness of the voice. I have no means of indicating this by instruments but it is readily detected by the ear. The defect is present in many singers and in nearly every case of abnormal speech; all epileptics and many stutterers have this laxness. It also occurs as an independent form of negligent speech. Large numbers of the children at Randall's Island have this defect with or without other speech defect.

The defect is due to insufficient closure of the glottis by the vocal cords. In most cases the cords are bowed open at the center. The most effective treatment is staccato singing, practicing notes on the vowel "ah," imitating the speech of the megaphone man, etc.

2. *Laryngeal Monotony.*—The vocal cords are stretched by several muscles. The tighter they are stretched, the higher is the pitch of the note. In singing they are stretched to a definite degree and the resulting tone is held steady. In speaking, the tone of the voice rises and falls at every instant, even in a single vowel. For example, if I say "How do you do" with a pitch indicated in the top line of Fig. 8, I speak in a perfect monotone, or chant. If I say it as indicated in the second line, I sing it. When I speak it, my voice rises and falls continuously as indicated in the last line.

To speak normally the laryngeal muscles must act quickly and readily. When there is the slightest awkwardness or stiffness, the tone will not rise and fall at every instant. The epileptic moves his muscles sluggishly and adopts a monotonous and flat melody. This is true without exception in every case of epilepsy I have ever seen. The habit remains after the fits have disappeared. It has been found it in the case of a valedictorian of one of our foremost colleges three years after the last fit and two years after the last dose of bromide. The defect is due to pure negligence in the nervous stimulation of the laryngeal muscles. In epileptics the fault can be corrected instantly. It is only necessary to point out to the patient the difference between his speech and the normal speech. He then speaks correctly. Epileptics usually do not care much about the character of their voices, and will

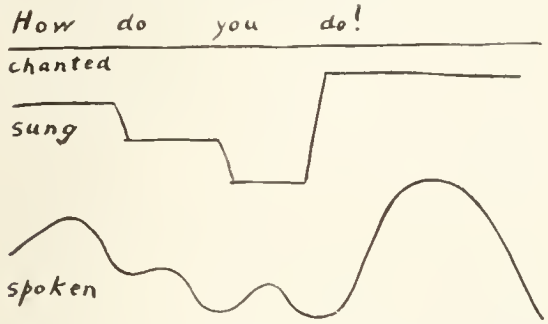

Fig. 8.

not take the trouble to keep up the correct melody. For private patients it is, however, important to remove the vocal defect that lets every one know that there is something queer about them.

Stutterers also have a monotonous speech which usually falls at the end of each sentence by a minor third. This gives a melancholy tinge to their conversation. I know one little girl whose voice moves in a most melancholy melody although she is perfectly happy. The laryngeal monotony in stutterers is due to excessive tension of the laryngeal muscles; it is not a defect due to negligence; I have discussed it in a previous paper.

Ear Defects.

Many children cannot speak properly because they do not hear properly. Up to the present all I have done for such cases is to teach them the various sounds while talking very loudly. I also let them see that for "m" my lips come together, that for "t" the tip of the tongue is raised, etc.

Nervous and Mental Defects.

1. *Inattention.*—Inability to fix the attention long enough to learn a sound naturally leads to incorrectness of the most varied kinds. Here is a little boy who can say "b" perfectly in the word "baba"; but he says "hoy" instead of "boy." No amount of repetition makes any difference. You tell him to look at your lips while you say "boy," but you notice that before you can get started his eyes wander away. It is the same way with "m," "t," etc. What is to be done? Here is the method I have employed. A little rubber bulb (Fig. 9) is

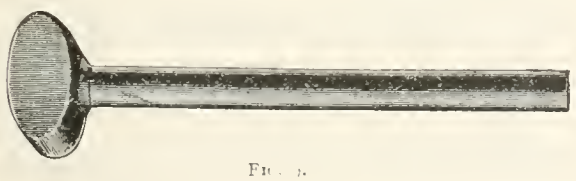

Fig. 9.

placed between the lips. It is connected to an indicator of the kind described above (Figs. 6, 7). The patient is shown that when he presses the bulb with his lips the indicator moves. He must then say "boy" in such a way as to move the indicator. To teach the correct tongue action for "t," "k," etc., the bulb is placed at the proper point in the mouth.

2. *Hastiness.*—In nervous children there may arise a habit of speaking so quickly that the speech becomes jumbled and defective. The patient then loses his correct notions of sounds, or, if the trouble is with him from the start, he gets only incorrect ones. He must be taught to speak slowly, *e.g.* by

reciting verses of which each word is printed on a card and turned over singly. He is also trained to make each sound of the language clearly and distinctly.

General Considerations.

Not long ago there appeared at the Vanderbilt Clinic a teacher with ten stuttering boys behind her and a list of thirty other stutterers and lispers from the same school who were to arrive in the next consignment. I was forced to say to her that my clinic was already as large as I could handle, and that the addition of forty more from each school in the city—that is a total of, say, 8,000—would make too great a load.

What is to be done with the 25,000 stutterers and lispers in this city? Stuttering is a distinct form of nervous disease, as I showed in my previous paper; it can be properly and legally treated only by a physician. Negligent speech can also be best treated by the practitioner. The care of a specialist is needful only in obstinate cases. The methods required for most cases can be made, as I have shown you in my two lectures, so simple that a physician or a medical student can learn them in six or eight exercises. Courses should be provided in our medical schools. Until this is done nothing will give me greater pleasure than to demonstrate the methods at the Vanderbilt Clinic every Wednesday and Friday to any physicians who will do me the honor of attending.

87 Madison Avenue.

THE HOSPITAL AND THE PROFESSIONAL ANESTHETIST.

By ALGERNON T. BRISTOW, M.D.,

Brooklyn, New York.

The hospitals of any community usually represent the best in medicine and surgery of which the community is capable. Even in those happily rare instances where politics exerts an influence in the matter of appointments, although political influence may play some part in the way of preference, the professional politician will rarely be found urging the appointment of a manifestly unfit or incompetent candidate. He may have his choice, but in the experience of the writer it is between the fit, and not between the fit and the unfit. Thus we carefully guard the portal of our hospital wards and seek to secure for the sick the highest degree of skill attainable in the visiting staff. There is one important part of our hospital work, however, which has been for many years entirely neglected. At least we have taken little pains to see that it has been in competent hands. I refer to the administration of anesthetics. That this is an important part of our work does not seem to need argument or proof. The administration of a general anesthetic is always a misfortune, even when well done. Under our present system it is too often a calamity, which proves to be without remedy. How often do we hear it said that the patient is too weak to stand an anesthetic; how often does the very life of the patient hang on the method of anesthesia, or rather in the manner in which a particular method is used, whether intelligently or carelessly. Hospitals exercise the greatest care in the selecting of the visiting surgeon. How many hospitals have a visiting anesthetist? I should like to ask the visiting surgeons in our hospitals were they themselves or a member of their families to be the patient whether a young house officer recently graduated would be their choice for anesthetist. I have not found it so. Why, then, should we treat the patients in our wards in any manner different from that in which we would be treated ourselves? Why select an expert for one part and a tyro for another part of the work which in effect may be of vital importance? It is a fact that at least until very recently in all hospitals and even now in most hospitals the anesthetic has been entrusted to a member of the house staff, usually the junior. Even when the anesthetist has been of higher grade than this, he has still been a member of the house staff and of little experience for the important work entrusted to him. What he knows is largely the result of theory aided by a rather limited observation. That serious accidents do not happen more frequently is strong testimony of the intelligence and care of our young house officers. But serious consequences from the anesthetic do not occur on the operating table alone. A patient may die from an anesthetic badly given long after the ordeal of the operation is passed. Ether pneumonia, ether shock, postoperative vomiting of obstinate character all follow in the wake of an improperly given anesthetic. There are many questions regarding anesthetics which the skilled man can answer, but which the young interne either is not allowed to answer or is incapable of answering. Chloroform is far safer in some cases than ether, and ethyl chloride or gas than either of the others. Shall I willingly entrust the administration of so powerful and tricky an agent as the first named to a tyro, even when it is indicated? Should I do so? How much of the agent used should be given to maintain surgical anesthesia per hour? It means a great deal to the patient not to have been over saturated with a narcotic vapor. It means much to the comfort and freedom of the surgeon to have his patient always sufficiently under the influence of the anesthetic as to be quiet and yet not too deeply narcotized. It has been too common in the past and is still too common for the operator to be compelled to keep one eye on the man with the ether cone and the other on his work. As a result of this bad system it often happens that the narcosis is either insufficient at critical moments or needlessly profound or the patient stops breathing altogether and all hands proceed to artificial respiration. We have all of us seen such scenes, yes, and been actors therein much oftener than we would willingly admit. Nor do these facts apply to New York hospitals alone. While writing this paper, the writer received a reprint from Dr. John B. Roberts of Philadelphia, entitled "The Anesthesia Peril of American Hospitals." When a man of Dr. Roberts' weight and conservatism thinks the facts justify such a title as this, it is high time that we woke up to the evils in the present system and set about their correction.

It is not the intention of the writer, however, in discussing this subject to depend on bald assertion. Not that he believes that the profession will seriously dispute the truth of the statement that the present system is faulty. He prefers to offer some statistics which it seems to him carry their own conclusions. In a broad way a fair method of comparison as between the methods of the professional anesthetist and the less trained hospital junior would be to contrast the amount of ether used by the two classes of men. When one averages up a large number of cases the amount used per hour would be as fair a test of the efficiency and skill of the administrator as any rather rough and ready means could be. From the hospital standpoint the man who can use the smallest quantity of a drug which is rather costly and get the required results

is better from the economical standpoint than a man who uses twice or three times the quantity. From the standpoint of the patient, that individual who receives twice as much ether as is necessary to maintain surgical anesthesia is far more likely to suffer from the unpleasant after-effects of the anesthetic than a patient who receives just enough and no more. We desire to submit the following figures which have been collated for us by the kindness of Dr. A. F. Erdmann, anesthetist to the Long Island College Hospital. First, we include fifteen replies received from members of the Brooklyn Society of Anesthetists, tabulated and averaged as follows:

Ques. 1.—How long does it take you to induce an anesthesia?

Straight ether:

Shortest time, 2 minutes; average shortest time, 4½ minutes.

Longest time, 15 minutes; average longest time, 10 minutes.

General average time, 7¼ minutes.

Ether preceded by gas or ethyl chloride:

Average time, 3½ minutes.

Ques. 2.—How much of the anesthetic do you use in the induction?

Straight ether:

Smallest amount, 90 grm.; average smallest amount, 40 grm.

Largest amount, 90 grm.; average largest amount, 75 grm.

General average, 60 grm.

Ether preceded by gas of ethyl chloride.

Average amount of gas, 4 gal.

Average amount of ether, 25 grm.

Ques. 3.—How much of the anesthetic do you use for one hour?

Smallest quantity, 75 grm.

Largest quantity, 180 grm.

General average, 150 grm.

Vapor method, 90 grm.

For the purposes of comparison I place in juxtaposition the following statistics from hospitals which I designate by letter. Here I condense somewhat and restrict the figures to the quantity per hour.

A.—57 ether anesthesias, one anesthetist, no alcoholics; open methods, Esmarch's mask. Quantity per hour, 281 grams.

B.—100 anesthesias, ether preceded by gas, Allis inhaler. Quantity per hour, 297¼ grams.

C.—100 ether anesthesias, Fowler inhaler. Per hour, 325 grams.

D.—500 cases, Allis inhaler. Per hour, 336 grams.

E.—100 cases, Allis inhaler. Per hour, 435 grams.

F.—100 cases, 375 grams.

The figures from the Society of Anesthetists include about 10,000 cases. The hospital figures about 900. The amount of ether per hour as given by members of the house staff in the hospitals more than doubles the average quantity used by the professional anesthetists—341 grams per hour, as against 150 grams per hour. These figures may be interpreted in either of two ways, neither of which, however, is a credit to the system. The ether is either wasted by the use of large quantities by the open method, with a consequent loss from evaporation—which is, of course, bad economy for the hospital; or the patient gets far more ether than is required, which is a bad thing for the patient. Whether the first deduction be true or not, there can be little doubt of the truth of the latter. Perhaps both are true.

It seems fair to conclude, from what has been said, that there really is just as much reason for appointing a visiting anesthetist to a hospital as for making any other professional appointment on the staff. It is necessary to provide for two things in making such an appointment: In the first place, the internes must receive the instruction to which they are entitled as a part of their hospital training. It is far better, however, for them to receive this instruction at the hands of an expert, than to learn by experience at the expense of the patient and the patience of the operator. Also, it is absurd to expect a man to attend long hospital clinics as anesthetist, if he is not in some way to get remuneration for his services; for if he is to be of value to the hospital he must be a specialist in the administration of anesthetics; and if he is this he cannot do much private practice for his livelihood.

As for the anesthetist, then, there are two ways of providing for him: The hospital may pay him a salary, which he may supplement by private work in the same field. This is done in both Philadelphia and Boston. The hospital may recoup itself by making a regular charge to all private patients for the administration of the anesthetic. Another method would be for the anesthetist to receive his payment directly from all private patients operated on in the hospital. Some arrangement of this sort is evidently necessary if we are to expect any real reform in our methods.

We should have recognized long ago, and ought to recognize now, the peculiar value of skilled work in this field, which consists in the ability of the anesthetist to make a proper choice of the method, the agent, and to recognize the necessity of changing either or both at any time. Also, the ability to gauge the proper amount of the agent to be used and the ability to recognize any abnormal symptoms and to meet the emergency promptly. As a member of the Society of Anesthetists said to me—willingness to see and know nothing except the anesthesia, is an essential characteristic of a good anesthetist.

To keep in good condition for good work necessitates doing much work; to do much work means being unable to do much other work. It seems only fair to give the work to the man who deprives himself of other income to enable himself to be the best workman.

234 Clinton Street.

THE IMPROVEMENT OF GENERAL ANESTHESIA ON BASIS OF THE PRINCIPLE OF ADAPTING THE BOILING POINT OF THE ANESTHETIC TO THE TEMPERATURE OF THE BODY (SCHLEICH)—TEN YEARS' EXPERIENCE AT THE GERMAN HOSPITAL.

By WILLY MEYER, M.D.,

NEW YORK.

PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN HOSPITAL; CONSULTING SURGEON TO THE NEW YORK SKIN AND CANCER HOSPITAL AND NEW YORK INFIRMARY.

As is well known, Schleich attempted to improve general anesthesia on a physical basis, namely, by adapting the boiling point of the narcotic to the temperature of the body. Of course, he did not ignore any of the other important points in administering the anesthetic: careful preparation of the patient, drop method, etc. Schleich, by the way, is the same surgeon who originated the solution for local anesthesia known under his name, and now used the world over.

Chloroform has a boiling point of 149° F.—con-

siderably above the body temperature; ether, one of 93.2° F.—somewhat below the same. Therefore, Schleich argued, that chloroform, when administered for narcosis, is absorbed by the blood in larger amount than is necessary for the purpose. It leaves the organism only by degrees and, in doing so, overtaxes all the parenchymatous organs, especially heart, kidneys and liver, thereby injuring their cells.

Ether, on the other hand, with its boiling point of 93.2° F. is converted into vapor so rapidly when inhaled into the lungs with their temperature of 100.4° F., that it would not enter the blood at all—loosely bound as it is—if the alveoli did not first become overfilled with carbonic acid gas, producing primary cyanosis and dyspnea. It is with the onset of this cyanotic condition, it seems, that the narcotic effect of the sulphuric ether begins. Although the elimination of ether almost keeps pace with its absorption, the slight excess that remains in the blood is sufficient to affect the brain and produce unconsciousness. The greatly accelerated rhythm of breathing, which increases the amount of oxygen inhaled, facilitates the elimination of carbonic acid, by the laws of diffusion of gases involved in normal respiration. Incidentally the elimination of ether is also facilitated. For this reason death from ether on the operating table is almost impossible, as long as respiration is efficient.

On the other hand, all these processes just described account for the fact that ether narcosis sometimes has such deleterious effects on patients suffering from lung trouble. The primary and altogether essential condition for the regular elimination of the ether vapors is an absolutely intact lung—a lung that is able, if necessary, to do more than the usual amount of work.

On the strength of this reasoning, supported as it was by practical experience with chloroform and ether, Schleich started out to find a safer narcotic which would not tax the parenchymatous organs of the body, nor the lung tissue, and the boiling point of which would correspond to the temperature of the body, so that the amount eliminated during expiration would be about equal that absorbed during inspiration. Such new anesthetic, he was convinced, could be found in a combination of anesthetics only. After considerable experimenting, he finally selected chloroform, sulphuric ether, and petrolic ether (benzin), the latter with a boiling point equal to that of chloroform, i. e. about 149° F. The action of the latter, as Schleich himself stated, is indifferent as regards any narcotizing effect; it was added merely for the purpose of diluting the chloroform; that is to say, with the idea of diminishing the latter's poisonous effects upon the system. He used three mixtures, the boiling point of which ranged between 100° and 107° F.

That 43 parts of chloroform and 57 parts of ether when mixed form a stable molecular *solution* with a boiling point of 125° F. was determined by the late H. P. Weidig, Ph. D., of Newark, a fact which Schleich does not seem to have been aware of. This solution constitutes an excellent anesthetic.

On analyzing Schleich's mixtures, Dr. Weidig found that they contain this fixed molecular solution of chloroform and ether, plus 36 to 53 per cent. (in volume) of free ether, plus petrolic ether, both the latter most probably not in chemical combination. Therefore, patients subjected to general anesthesia by means of Schleich's mixtures, inhale in the beginning of the narcosis pure ether plus the molecular solution, plus petrolic ether. After the ether and petrolic ether have become evaporated, the narcosis continues with the molecular solution, which has a boiling point of 125° F.

This petrolic ether which Schleich, unfortunately, selected as the third ingredient of his mixtures, not only has no narcotizing power, but, according to the experiments of Dr. S. J. Meltzer, of New York, produces paralysis of the respiratory muscles, if administered in larger amount.

Considering Schleich's principle of improving general anesthesia on a physical basis to be correct, being unwilling, however, in view of Dr. Meltzer's findings, to accept the mixtures proposed by the former, Dr. Weidig and myself after numerous experiments during 1897 and 1898 tried ethyl chloride with a boiling point of 59° F. as a substitute for the petrolic ether, and found that 17 per cent. volume of ethyl chloride mixed with 83 per cent. volume of the molecular solution of chloroform and ether, reduces the boiling point of the latter solution (125.6° F.) to 104° F.* The three substances, chloroform, ether and ethyl chloride, in the proportions stated, form a chemical combination, not a mixture.

This chemical combination was trade-marked "anesthol" by the manufacturers, much against my will.

Anesthol has a specific gravity of 1045, which is very close to that of the blood (1056-1059). According to volume, it contains 17 per cent. of ethyl chloride, 35.89 per cent. of chloroform and 47.11 per cent. of ether, representing, as will be seen, a proportion of about 1:2:3.† For a complete description of the drug and its effect, I would refer to my former article in the *Journal of the American Medical Association*, February 28, 1903.

I have used this preparation in my hospital and private work for the last ten years (for the first time Oct. 15, 1898). It is also extensively employed by my colleagues at the German Hospital. Early in the fall of 1899, we introduced the rule of giving a hypodermic of morphine about one hour prior to the administration of the general anesthetic. We had learned by experience that in this way anesthesia is much more speedily induced and, besides, less of the narcotic is required in the course of the operation. We try to keep the patient just sufficiently under the influence of the drug to render him unconscious and thoroughly relaxed, but ready to wake up very soon after the administration of the narcotic is discontinued.

With this anesthetic, administered by means of the drop method and an Esmarch inhaler, the gauze of which is covered by some impermeable material with a cut-out in the center, it will be observed that

1. Surgical anesthesia is established in the majority of cases in about eight minutes. If mor-

*It had been found in course of the experimenting that, according to the amount of ethyl chloride added, the boiling point of the combination could be varied. We selected the proportion above stated, giving the solution a boiling point of 104° F., experience having shown that of an anesthetic with a slightly higher boiling point than the body temperature less is required than of one that exactly corresponds to the same. Lately Schleich has also adopted this combination, substituting ethyl chloride for petrolic ether. He again proposes three different mixtures, which, however, is not practical.

†It certainly is of interest and worthy of note that the proportion of the renowned English A. C. E. mixture is the same. The latter, however, was constructed in an empirical way, while the mixture of chloroform, ether, and ethyl chloride is based on scientific principles, being the result of an attempt of adapting the boiling point of an anesthetic chemical combination of chloroform and ether to the temperature of the human body.

phine is previously administered, even this time is very frequently reduced by a few minutes.

2. The stage of excitation, if it sets in at all, is of very short duration.

3. Complete anesthesia, having been gradually induced, the pulse is full and slow,—of the chloroform-anesthesia type—and respiration regular, not stertorous.

4. In no instance has there been an increase in salivation or bronchial mucus during narcosis.

5. The face presents a healthy color. There is no pallor nor cyanosis.

6. If too little of the anesthetic is given, the patient will begin to gag or vomit, as with chloroform; if too much is administered, respiration will become shallow and, eventually if still more is poured on the mask stop altogether, but the pulse will not be interfered with. In other words, the respiratory and not the circulatory center is first affected by an *overdose*. There is, therefore, not the danger of the dreaded syncope, as with chloroform. The tendency throughout the narcosis is toward recovery from the effect of the anesthetic, not toward a profounder anesthesia; hence the advisability of administering it constantly, at a suitable rate and drop by drop. Of course, a careless narcotizer can kill a patient with this as well as any other anesthetic.

7. After the anesthetic has been stopped, the patient soon comes to, sometimes even while still on the operating table. If he sleeps longer, it is usually on account of the previously administered morphine.

8. Vomiting occurs in a small percentage of cases after return to consciousness. It is, however, not of a prolonged or distressing type.

9. Untoward aftereffects, such as bronchitis, pneumonia, nephritis, are not seen as a result of anesthesia with this mixture. A preexisting catarrh of the bronchi or inflamation of the kidneys may, of course, become somewhat aggravated for a few days, but never to the extent as happens after the inhalation of other gaseous substances. These complications certainly are never produced by this anesthetic.

10. Patients afflicted with serious valvular cardiac lesions, chronic pulmonary affections, atheromatosis, diabetes, profound anemia or other complications of serious character, have stood this preparation most satisfactorily; contrary to what one would be justified in expecting in such cases, a better circulatory and respiratory condition was induced during anesthesia.

11. The total quantity used is generally small. Our narcotizers very often carry a patient through an anesthesia lasting from one to two hours, with two to three ounces.

There are other interesting characteristics of this anesthetic agent. It would lead me too far, however, to enumerate all of them here to-night.

*Note at time of correcting proof: Every general anesthesia is a temporary poisoning of the system, hence vomiting can never be entirely avoided. We are able to reduce it in frequency and severity, however, by means of improving general anesthesia as such. It will be worth while to try in this respect the method recently proposed by C. Ritter in the *Centralblatt für Chirurgie*, July 11, 1908. He makes a rather pronounced degree of head hyperemia with the elastic neckband at the completion of the operation, and has seen, at least after superficial ether anesthesia, that vomiting then did not set in. It certainly would be most interesting if experience should prove that Bier's artificial hyperemia can also bring improvement in one of the most distressing after-effects of general anesthesia.

We have used the chloroform, ether and ethyl chloride mixture* in many thousands of cases at the German Hospital within the last ten years and consider it, when preceded by a hypodermic of morphine, the least dangerous of all anesthetics thus far known, especially in the hands of comparatively inexperienced anesthetists, and this not only as regards the safety of the patient while on the operating table, but principally as to the after-effects of the anesthetic.

The value of the improvement of general anesthesia brought about on the principle of adapting the boiling point of the anesthetic to the temperature of the body has, I think, been sufficiently demonstrated to merit the full and careful consideration of the profession.

700 Madison Avenue.

ANESTHESIA AT ST. LUKE'S HOSPITAL.

By ROBERT ABBE, M.D.,

NEW YORK.

The importance of anesthesia is ever present in the mind of the surgeon and often brings up for discussion the question of a permanent anesthetist in the general routine of hospital work.

The two ruling motives in the conduct of institutional work are (1) subserving the patients' best interests; (2) thorough training of the ever changing corps of intelligent resident doctors and nurses. The only *constant* factor in the professional work is the surgeon in charge, who gives his experience year in and year out for a lifetime, often. At St. Luke's Hospital we have always been inclined to consider the etherization of the patient as one of the surgeon's important responsibilities. To watch and to teach, is as much a part of his work as to operate. The rôle of the general surgeon must remain supervisory in the highest degree.

Each year the younger surgeons leave their service equipped to go here and there over the country, trained to use the experience there acquired. There is no more important part of their training than a knowledge of the seriousness of giving ether.

The idiosyncrasies of the patient, the nature and effect of the anesthetic itself cannot be taught by books alone. Day after day patients are seen, each one differing in disease, in vital force, in severity of the operation. This one is an old alcoholic, the next a feeble elderly woman, then a little child.

One lies down and inhales ether is if going to sleep; the next fights for time as a coward; the third is frightened almost to death, before starting in, and has to be hypnotized to quiescence by the kindly or ingenious and soothing suggestive words of the etherizer.

Never shall I forget an old sailor many years ago who came to the etherizing room so frightened because it was Friday, that his trembling, pallor, faint heart, and terrified appeals absolutely forbade my proceeding in the face of the same degree of shock, "moral shock," which in operating might have cost him his life.

Quite recently I had to postpone indefinitely an operation upon a frail lady, advanced in life, who gave evidence of low vitality at the onset of ether-

*It should be stated that while we use this preparation in nearly all cases, we also employ local and spinal anesthesia wherever these are indicated. A fact which deserves special mention is, that alcoholics, too, can usually be brought fully under the influence if the anesthetic is preceded by a hypodermic injection of ½ grain of morphine. Only in very exceptional cases was chloroform needed. The use of ether has been entirely discarded by us.

ization, instead of the usual stimulating effect. The jaw dropped, the skin showed relaxation, the cutaneous capillaries blanched and a waxy cadaveric appearance ensued which, I felt sure, would have resulted fatally had the shock of operation been superadded. Yet her heart action seemed adequate. The watchful care of the surgeon is given with paternal solicitude and is an invaluable asset in the education of the younger surgeon. Not only the operator, but the senior and other assistants, who have received the same drill, are ever watchful of the patient's welfare.

It soon comes to be understood that safe anesthesia is maintained only when the patient is not given too much. When the saturation point is reached, the etherizer is taught to keep the patient simply asleep.

It frequently happens that one of the superior officers, who is always present, gives much needed aid in moments that might be perilous—even in anesthesia by ether, which is universally admitted to be the safest agent. In this way the danger is reduced to almost nothing, but it is only by safeguarding the unconscious patient, that mishap can be averted. It may be fairly said there is no anesthetic yet known, by which a fatality may not be invited if closest scrutiny of the patient and supervision of the anesthesia is not maintained. Therefore it becomes as much the imperative duty of the surgeon to impart the training in anesthesia as in surgical technique to his staff of resident assistants. Undoubtedly the ideal condition is in having a specialist in anesthesia always present. For obvious reasons this is impossible in all conditions of practical surgery. Thus conducted, our hospital patients are safeguarded; were it not so, one could not conscientiously carry on the grave responsibilities of the care of the public.

In a continued service of twenty-four years at St. Luke's, speaking only for my own work, I have seen but two deaths directly from the anesthetic in perhaps twelve or fifteen thousand anesthetizations. One occurred under chloroform—which I rarely use, but which was chosen because of the extreme atheroma of the old man's arteries. He had undoubtedly myocarditis, which was not identified beforehand, though his heart, as usual, had been carefully examined. After a half hour's operation he succumbed to heart failure in spite of prolonged radical efforts to revive him. One other death can be credited to ether, in a woman, who in much the same way failed to rally at the end of a prolonged operation for extensive mammary cancer. I can truthfully say that no other death from *anesthesia directly*, has ever come under my notice.

The greatly improved method of giving nitrous oxide gas prior to ether by the admirable inhaler of Dr. Bennett has my unqualified endorsement, and has been universally adopted for many years. We have tried to initiate the staff in the so-called "drop method" from time to time, but have given it up as time consuming and often failing in efficiency.

The Crile method of anesthesia through nasal tubes, packed about with gauge in the throat, is always adopted in bloody operations about the head, and is greatly to the advantage of the surgeon and patient.

Finally the widening use of cocaine and novocaine with adrenalin, which reduces their toxicity to a minimum, has given advantages in operating which cannot be realized by those who have not tried them. It often happens in major operations that a very few whiffs of ether will carry a patient through when cocaine is not quite adequate—and thus profound anesthesia is unnecessary.

Spinal anesthesia I have resorted to but seldom—believing that as yet its relative safety is not established, and we cannot rightly experiment on our confiding patients—unless the peril of general anesthesia is greater in the particular case in hand. Finally I place the greatest importance on an entirely empty stomach for anesthesia. If vomiting or gas distention has preexisted gastric lavage is imperative. Under other circumstances, if, at the end of operation the patient regurgitates fluid deeply bilious, as occasionally happens, one should insist on stomach washing, inasmuch as bile retained in the stomach seems to have a peculiarly depressing and poisonous effect.

The advantage of the subsequent study of cases which the staff follow in hospital, added to the very frequent anesthetizations by the master expert on private cases, seems to me to give a practical solution to the correct hospital service.

13 West Fiftieth Street.

THE ADMINISTRATION OF ANESTHETICS AT MT. SINAI HOSPITAL.

By Howard Lilienthal, M.D.,

New York.

In December, 1886, when I had served my first day as the lowest member of the house staff of Mt. Sinai Hospital, one of my senior surgeons requested me to anesthetize an old man for the reduction of a dislocated shoulder. I had just come from Boston, the home of ether, and was considerably frightened at the idea of administering chloroform which I had been taught to look upon with dread. "You'll have no trouble," said the surgeon, "just take this mask, hold it about an inch from his face, pour on the chloroform a few drops at a time, and I'll do the rest." For me it was like the commission of a first sin, and, as is usually the case with those who sin for the first time, no punishment was forthcoming. An easy, pleasant primary anesthesia, the surgeons' stockinged-foot in the patient's axilla—an atrocious method even then—and in a few seconds the little operation was finished with the patient awake and the dressing in place. It all seemed very easy, and I began to have my first distrust of my Harvard teaching that ether was good and chloroform wicked.

A short time afterward the house surgeon performed an operation for the relief of strangulated hernia in an old man, emphysematous and asthmatic, and I administered ether, using the old-fashioned Allis' inhaler, drenching the apparatus with many ounces of the anesthetic and closing the open end in order the more quickly to secure narcosis. Throughout the operation the breathing was labored and stertorous, with a loud wheeze at the end of expiration. The breathing became even worse after the operation, the patient's lungs seemed flooded with secretion, and in a few hours death came. It seemed even to my inexperienced observation that the ether was certainly to blame.

Gradually chloroform became my favorite anesthetic, for in spite of statistics, its dangers seemed exaggerated. Then, one day, a young strong man, with an abscess of the neck, died after a few inhalations of the drug—by great good fortune not administered by me. Again, but some years later, an old man with intestinal obstruction, succumbed soon after the beginning of an operation under

chloroform. It seemed as if the postoperative dangers of ether were after all preferable to the sudden shocking end of all things on the operating table. You felt that you at least had a chance to do something for the patient in pneumonia or nephritis, while in chloroform syncope the fatality was there almost before you knew it.

From the beginning of my serious operative work my principal anxiety has been the narcosis, but extended observation has led me to conclude that an immediate death, whether due to ether, chloroform, or any other general anesthetic, almost never occurs when the anesthetist is expecting it. It has been my habit to impress on the men of my staff that if they keep constantly before them the idea that the particular patient in hand is in danger of dying on the table, such a calamity will probably be avoided. Even in those cases in which the death occurs in the very beginning of the narcosis, there are warnings which the more careful or "timid" anesthetist will note and heed. One of the best men I know began his duties with such obvious lack of self-confidence that it was painful to watch his work. Gradually his assurance became established, while the carefulness born of his timidity remained. He had a wholesome respect for the responsibilities of his office which was very reassuring to the operator.

The advent of the specialist in this branch of the profession, with his skill, great care, and experience, has given to the surgeon a new sense of security, yet it must not be forgotten that when fatality occurs no matter how much responsibility the anesthetist may be willing to shoulder, it is the surgeon's patient who has died and the surgeon's name which is connected with the catastrophe.

Following the old Allis's inhaler we had a brief period at Mt. Sinai when Clover's apparatus was used, with marked diminution of annoying symptoms and sequelæ. Then in the early '90's the gas-ether sequence made things more agreeable for the patient, but the nitrous oxide had to be followed suddenly by full ether inhalations, and frequently enough there was deep and long-continued cyanosis which was very disturbing. Not until the Bennett inhaler came was it possible to administer the sequence in a truly scientific manner.

At present, nitrous oxide, the gas-ether sequence, and chloroform, or their various combinations are practically the only general anesthetics in use at Mt. Sinai Hospital. The selection is made by the surgeon if a member of the house staff is to be the anesthetist, but when we are fortunate enough to have the services of a specialist he usually selects the drug after being put in possession of the important facts in the case. By far the greater number of anesthesias are begun with nitrous oxide and ether, afterward changing to chloroform if respiratory disturbances seem to demand it. Chloroform given after the patient has been put to sleep with the safer drugs does not appear to be so dangerous as when it is primarily administered. Again I repeat, however, that chloroform, *skilfully given in suitable cases* has proven itself thoroughly satisfactory. In tumors and abscesses about the neck, especially when the air current is ever so little impeded, this chemical seems to be particularly dangerous, as is also the case when the patient is terror-stricken. In pulmonary trouble chloroform is the anesthetic of choice and ether is greatly to be feared.

Nitrous oxide alone or mixed with air is excellent when ether or chloroform must not be used and yet unconsciousness is desired. In diabetics, and particularly in acetonemics, this is of especial value. Indeed, acetone is not a rare constituent of the urine after the absorption of the anesthetics, especially chloroform, even in persons supposed to be constitutionally healthy.

In 1884 I first saw ether administered by the rectum in the Boston City Hospital. We tried it at Mt. Sinai for a few years, but discarded it because of the danger of proctitis in spite of washing out the superfluous gas, and because of the slow absorption and still slower elimination of the drug, rendering the control of the narcosis very doubtful and much inferior to that obtained by inhalation. As to the present method with pressure gauge, it appears to me that little is gained over the old way. Ether at the same temperature is pretty apt to liberate vapor at the same pressure.* I remember at that time we had several bad "scares" and deaths were reported in the literature. It requires very large numbers of cases for us to deduce valuable statistics of anesthesia. One hundred or five hundred cases without a death means very little to the surgeon.

A few of our men have employed spinal analgesia with varying success. I have never given it a trial and fear it less for its danger to life than for the more or less permanent injury which it may inflict. Paraplegia and incontinence of feces are not agreeable sequelæ to an operation designed to make life more comfortable.

Local anesthesia, the discovery of Carl Koller, at at present one of the surgeons of Mt. Sinai Hospital, continues to prove its great usefulness. Koller is known to be the discoverer of the surgical application of cocaine, but he is more than that—he is the discoverer of local anesthesia.

Gastrostomy for esophageal stenosis if performed under ether or chloroform is nearly always followed by an aspiration pneumonia, frequently fatal. With local anesthesia the operation is safe. Diabetics and arteriosclerotics are bad subjects for local anesthesia by subcutaneous injection because sloughing is apt to follow. In aneurysm of the large thoracic vessels Wyeth has ligated the subclavian artery with the aid of cocaine alone.

But I need not proceed farther in this strain, since the usual indications for the various drugs and methods are well known to all. The principal thing is the recognition of the extreme responsibility of the anesthetist's work. To set an untaught junior this serious task is not fair to him nor to the patient. We have certainly progressed in this respect. For the past five or six years we have made it a rule that a man of some experience must be present together with the junior at each anesthetrization. I am glad to say, too, that our Board of Directors have recently made a generous provision for two paid anesthetists to serve continuously as principals or instructors for the first two of every six months when the house staff changes. It has been noted in the past that at the time of this change of staff there is an especial liability to accidents, and it is hoped that with the creation of this important new office our nerves may be spared and the lives of our patients saved.

115 East Seventy-third Street.

*Note: It is perhaps not quite fair for me to express an opinion on the new method of rectal etherization, for the reason that I have never tried it.

Kidney Tumors.—Sarcoma of the kidney is generally accompanied by pronounced emaciation, hematuria, and a moderate grade anemia, whereas congenital cystic kidney seldom causes much emaciation and rarely hematuria.—*Southern Medicine and Surgery.*

ANESTHETICS AT THE HOSPITAL FOR RUPTURED AND CRIPPLED.

By V. P. GIBNEY, M.D.,

NEW YORK.

Among the first in this city to employ one skilled in the administration of anesthetics was the Hospital for Ruptured and Crippled, and among the first of the operating-rooms to give Dr. Bennett an opportunity of demonstrating the value of such service was the one at the hospital I represent this evening.

The reported safety of chloroform as an anesthetic in children was long before this date discredited among the members of our staff, and ether, despite its many drawbacks, has persistently held its own in all of our major operations. An operating-room was provided for the first time in the winter of 1887-8, and while minor operations were performed during the early years of the hospital, say from 1865 to 1887, anesthetics were administered very sparingly and not often beyond the primary stage. In explanation of this statement, let me say that prior to 1888 the mechanical side of orthopedic surgery prevailed to the exclusion of the operative, and achillotomies and fasciotomies were performed as adjuncts to the better employment of apparatus. Herniotomies were never performed in those days. But when active operative surgeons were added to the staff, an operating-room became a necessity.

The junior assistant, fresh from the medical school, in our earlier years of operative work, was the anesthetist, and the operator was unable to give his entire time and attention to the site of operation. We have, during the last decade or two, appreciated the value of having an anesthetist properly trained at the head of the patient. The title given to the officer was and is now, Anesthetist and Instructor in Anesthetics. It is his duty to instruct the members of the house-staff and particularly the resident junior in the principles of anesthesia, to stand by him and give real clinical instruction. He is held responsible for whatever agent is employed. He is selected usually from a number of candidates, and the salary was found a necessary incentive. As emergency work is not a feature in a hospital for chronic invalids, we can get along with two operating days a week, one for the orthopedic and one for the hernia work. Hence the service of the anesthetist is not required more than five or six hours a week, but those are very active hours, as two tables are under his divided supervision. From six to twelve operations are performed on the orthopedic days and from four to eight on the hernia days. A resident student is under instruction at the same time, and as his time of service extends over three or four years, he becomes a valuable aid to the chief.

After various attempts to secure accuracy in records, we have finally come down to an anesthetic-card, which is begun in the ward by the house-surgeon, is pinned on the breast of the patient before he is taken to the waiting-room of the operating-suite, and is completed by the anesthetist. From this the appropriate column in the operating-book is filled out and the card is pasted on the history sheet. With a large corps of assistants and nurses we are enabled to work expeditiously, and the aim of the operators, without an exception, is to shorten the time the individual patient is under the anesthetic. It seldom happens that the surgeon is not ready to begin just as soon as the patient is pronounced "ready," and the final preparation of the operating-room nurse is begun before the anesthesia is complete, believing as we do that these preparations assist materially in getting the patient "under."

The agents employed at present are, in order of their frequency, (1) ether, (2) nitrous oxide, (3) ethyl chloride, (4) somnoform, (5) chloroform. Prior to 1904 nitrous oxide was used to precede ether, and since that year kelen (ethyl chloride) has almost supplanted the nitrous oxide as a preliminary agent. We employ this in the wards as a local anesthetic and for minor operations on the older children and on adults, while ether to the primary stage is used in the very young children. Somnoform was used for a short period, but was discontinued because it was found to possess no advantage not possessed by ethyl chloride and because it was regarded as dangerous. Chloroform is rarely used at all and only when ether is contra-indicated.

Methods.—We begin with ethyl chloride in either the Esmarch or Bennett inhaler, and ether soon follows with the same inhaler, the towel cone, or the drop method.* The amount of ether required is from 5 to 6 c.c. in children, 8 to 9 c.c. in adults. The time required for full anesthesia is from 2 to 3 minutes with the Bennett and from 4 to 5 minutes with the Esmarch or with the drop method. During the last year and a half, morphine, grain ¼, and scopolamine, grain 1-100, have been administered 15 or 20 minutes before ether anesthesia is begun, in about 30 adults with very happy results. One-third the amount of ether was necessary. The duration of anesthesia in orthopedic operations is usually from 5 to 20 minutes, occasionally from ½ hour to 1½ hours, but these long operations are exceptional. The hernia operations occupy from 8 to 15 minutes, except in cases of double ventral or umbilical which last from 40 minutes to 1½ hours.

Casualties.—In looking over the records and consulting the traditions of the hospital, I find that there have been four deaths, 2 of which were undoubtedly due to the anesthetic, and 2 are doubtful. I present some of the details:

Case I. On February 27, 1894, a male child was anesthetized for a herniotomy. Five weeks before the operation the child had measles, and pediatrists have told us that the exanthemata lesson the resisting power, or to use a modern phrase, lower the opsonic index. This child took the ether very badly and developed pneumonia a day or two later, and died on the eighth day. The autopsy confirmed the diagnosis of double pneumonia. There was no infection whatever about the wound. So this may be put down to a postanesthetic death.

Case II. A girl, 4 years of age, was put on the table on July 28, 1899, for a preliminary stretching for congenital dislocation of the hip. Nitrous oxide was used and 10 minutes was the duration. The operation was completed, the cone was removed from the face, and a plaster-of-Paris spica was just under way when the child stopped breathing, and all efforts at resuscitation failed. This then may be put down as death from nitrous oxide.

Case III. On October 9, 1905, a little girl 7½ years of age, who had been in the hospital since April, 1904, suffering with Pott's disease, with compression paraplegia and abscess, was given ethyl chloride in the usual way, but died before we could

*We have found it very essential in the drop method to get the patient thoroughly anesthetized before the dropping is begun. It is then very easy to keep the patient anesthetized with the minimum amount of ether.

get her off the table. Her condition at the time was extremely poor, she was much exhausted, her nutrition was bad, and she had numerous bed sores.

Case IV. A boy, 4 years of age, was operated on in February, 1908, for hernia. Ethyl chloride and ether were administered and taken very well. Nothing out of the ordinary was noticed until the following day, when the child became depressed and exhausted and died four days later. No cause was found. Dr. Coley, who was in charge of the case and watched it very closely, came to the conclusion that it was a case of acetonuria.

16 Park Avenue.

AMPUTATION IN DIABETIC GANGRENE.*

By EUGENE H. EISING, M.D.,

NEW YORK,

ADJUNCT SURGEON, LEBANON HOSPITAL; ASSISTANT ADJUNCT SURGEON MT. SINAI HOSPITAL.

Several hundred years ago it was discovered in England that the urine in diabetes had a sweetish taste. This fact had however been known in India and since forgotten one thousand years previously (Wood). This simple technique of diagnosis has since fallen into disrepute and has been replaced by chemical methods. About one hundred years ago Dobson of England discovered that sugar occurred in the urine of most diabetics; this type of diabetes was later called diabetes mellitus. Such is the early history of one of the most difficult problems of biological chemistry.

During the last half century physiologists have been untiring in their application to the problem of the rôle of the sugars in tissue metabolism. Much of the physiology of the glycogenic function remains unsolved, but infinitely more of the pathology of that function. Advances in physiological chemistry have contributed much to our knowledge of diabetes mellitus, and by its aid we are in a position more accurately to determine the extent of the perversion of the metabolic processes in that disease.

I have set for myself the task of gathering and correlating the data obtainable in any case of diabetes with gangrene in order if possible to determine the standards by means of which one may more intelligently advise for or against surgical interference. This study I have based upon the material collected from twelve cases more or less carefully studied and from a free use of the literature. I shall refrain from incorporating in this rather theoretical essay the details of my own cases.

Consideration of the age, of the general condition, and of complicating disease while of extreme importance may be left out of this discussion.

I shall attempt to outline the rôle of the following factors and to attach to each of them their relative importance: (1) Glycosuria, (2) the acetone bodies, (3) ammonia excretion, 4) kidney complication, (5) arteriosclerosis, (6) blood pressure, and, finally, a summary of these factors in relation to gangrene.

The problem of the glycogenic function not only deals with the question of the occurrence of sugar and of its excess, and whether the aberration is one of increased production, or diminished consumption, but also, as Edsall states, "includes an inhibiting action preventing a flooding of the organism with acid substances elaborated from other carbohydrate materials." That sugar occurs in the blood under normal circumstances and in excess in diabetes has often been demonstrated. The blood of diabetics contains from 0.2 to 0.8 per cent. of sugar but rarely exceeds 0.5 per cent. Krehl estimates the normal glycemia for man at 0.1 per cent.

The blood of a normal dog, according to Herter, contains from 0.05 to 0.20 per cent. If this percentage be increased to 0.30 per cent. by intravenous injection of a glucose solution, the urine will contain sugar so long as there is an elevation of the sugar content in the blood. In other words the normal kidneys readily permit the escape of sugar so long as there is a hyperglycemia.

Herter furthermore makes the assertion that "it is clear that diabetes is not the consequence of an increased production of sugar. The alternative is that the disease depends on a diminished combustion of sugar in the organism, and there is no doubt whatever that this is the correct explanation of the increased sugar content of the blood." From our accumulated clinical experience it would seem that the mere presence of an excess of sugar in the blood is not of vital consequence, many diabetics exhibiting this phenomenon for years with but little discomfort.

On the other hand, however, Fritz Grossman has shown that the hyperglycemia in the presence of gangrene even though it be of low grade is a formidable factor inasmuch as this increased sugar content converts the body fluids and tissues into a more vulnerable medium for the invasion of pyogenic organisms. The hyperglycemia *per se*, however, is one of the more tractable factors and usually yields in large measure to diet and medication.

It seemed for a time that the key to the question of diabetic coma and of gangrene rested with the acetone bodies. These bodies, whose occurrence in the urine and formation in the organisms have been the subject of much investigation, occur in the urine especially in diabetes mellitus, but also in other diseases and conditions.

According to v. Jaksch and others, acetone is a constituent of normal urine, occurring in very small quantities (0.01 gm. in twenty-four hours). In regard to the origin of these bodies, there seems to be abundant evidence against the earlier ideas of v. Jaksch and Fr. Müller who considered the increase in acetone to be the result of an increased proteid destruction. To quote Hammersten: "At the present time the tendency is more and more to the view that the acetone bodies do not originate from the proteids but from the fats; if these are not the only source they are at least the most important." And Waldvogel states definitely that the acetone bodies originate from the fats which suffer in their oxidation just as do the sugars in diabetes.

To speak more definitely, the term, acetone bodies, according to Krehl, is used collectively for the three substances β-oxybutyric acid, diacetic acid, and acetone, which represent three stages in the process of oxidation of the same substances, and which under normal circumstances is carried to complete combustion, the final products being carbon dioxide and water. Acetone is not a very toxic agent, in fact it may be given, even intravenously, in quantities far in excess of that occurring in the course of diabetes without causing symptoms of toxicity. This fact would rather indicate that it is not a prime factor in the disturbed metabolism. That this substance is not a concomitant solely of diabetes has long been known. According to Kelly acetone occurs, besides in diabetes, in starvation, malignant growths, digestive disturbances, septic

*Read before the Metropolitan Medical Society of New York, May 26, 1908.

processes (general and local), infectious fevers, pregnancy with dead fetus, certain psychoses, autointoxications, chronic morphinism, phosphorus poisoning, injury to the cerebrospinal system, shock from injury, cases associated with fatty liver, uremia, and following anesthesia.

At this point it may not be amiss to digress in the discussion of acetone and look into its relation to anesthetics.

That acetone is the result of a disturbed fat metabolism is further suggested by the effect of chloroform and ether anesthesia upon its formation. It has recently been brought out that the anesthetic value of volatile substances is almost in direct ratio with their fat-dissolving powers. Young and Williams report that in fifty-two abdominal sections two patients had acetonuria before operation and twenty-seven in the same series after operation. In another series of seventy cases post-operative acetonuria was found twenty-six times. Stiles and McDonald have studied this question and conclude that acetonuria results from the decomposition of fats in the process of degeneration resulting from chloroform poisoning, the symptoms of chloroform poisoning being those of a toxemia produced by some of the antecedents of acetone in the process of the breaking up of the fats. This observation which is probably true in health, seems to be none the less so in diabetes. The increased fat destruction from the anesthetic acting in combination with the pathological fat metabolism of the diabetes, produces often a toxemia sufficient to determine a fatal issue.

Acetoacetic or diacetic acid has not been observed as a physiological constituent of the urine. It occurs in the urine chiefly under the same conditions as does acetone. Like acetone, acetoacetic acid occurs often in children, especially in high fevers, acute exanthemata, etc. It decomposes readily into acetone. According to Araki it occurs in all probability as an intermediate product in the oxidation of -oxybutyric acid in the body. This substance is a colorless and strongly acid fluid which when boiled with water or acids decomposes into carbon dioxide and acetone. The occurrence in the urine of β-oxybutyric acid was first definitely shown by Minkowski, Kulz, and Stadelmann. It occurs especially in severe cases of diabetes, when it may form the largest portion of the acetone bodies (Magnus-Levy, Geelmuyden). It has also been observed in scarlet fever, measles, and scurvy, and in some diseases of the brain. It seems always to be associated with diacetic acid.

β-oxybutyric acid usually forms an odorless syrup, but may be obtained as crystals. It is levorotatory and disturbs the polariscopic determination of sugar. It yields acetone on oxidation with chromic acid. It is probably the chief pathological acid occurring in the blood in diabetes, and being unburned in the body enters into combination with ammonia and appears in the urine. This acid occurs in abundance in diabetes, varying in amount from 15 or 20 gm. up to 60 gm. per day in severe cases.

It is more than likely that it is this substance that acts as a local poison in the tissues and contributes the baneful chemical factor determining gangrene. Klemperer divides diabetic gangrene into two varieties, the one without acidosis, and the other with acidosis. The former he finds amenable to dietary and medicinal treatment, and followed by demarcation and spontaneous amputation. The latter pursues a different course. Neither dietary nor medicinal treatment is of avail, and demarcation does not occur. He concludes that the patient's one chance lies in amputation.

This condition, properly named "acidosis," manifests itself by an increase in the excretion of ammonium in the urine, in that the acids which appear in the blood are combined with ammonium (Leube). The amount of the ammonia carried out of the system may be very large, and when the acid is so abundant as to exhaust the amount of available ammonia, other alkaline bases are called upon to supply the deficiency. These bases are, according to Herter, the sodium and potassium of the blood plasma and the calcium and magnesium of the bones. It becomes evident, therefore, that the amount of ammonia excretion gives us an approximate estimation of the pathological acid.

Ammonia is always present in normal urine. Spaeth finds that the quantity varies in health from 0.6 to 0.8 gm., but may rise to 1.2 gm. in the twenty-four hours. Under ordinary conditions the ammonia content of the urine varies with diet and drink and the air breathed. A meat diet raises, whereas a pure vegetable diet lowers the excretion of ammonia. A diet of radishes increases the amount of ammonia excreted as does also the inhalation of tobacco smoke and the ingestion of many drugs.

In the body ammonia comes chiefly from the disintegration of albuminous materials. The administration of acids increases the excretion of ammonia, owing to the attempt on the part of the organism to maintain within normal limits the chemical reactions of the fluids and tissues. The administration of alkalies on the other hand diminishes the excretion of ammonia. It must be added in this connection that the excretion of ammonia is increased in diseases other than diabetes, among which may be mentioned the large group of the infectious diseases, pneumonia, diseases of the liver, and many of the acute fevers. Phillips advises against operation, save in the greatest emergency, when the ammonia excretion in diabetes reaches 1.0 gm. in twenty-four hours. Spaeth, as mentioned above, states that this amount of excretion may occur in health.

Renal disease in diabetes is a complicating factor, and its etiological relation to the diabetes is not so readily determined. Several recent English authors have recklessly asserted that it occurs as a terminal result in the course of diabetes, being due to the irritation of the kidney epithelium by the unburned products of metabolism. This seems, however, not to be true. Simple epithelial changes consisting in glycogenic degeneration of Henle's loops and fatty degeneration or infiltration of the convoluted tubules are well known pathological changes in diabetic kidneys, but these pathological changes do not constitute a nephritis nor need they be accompanied by albuminuria. Upon this basis, however, a nephritis may supervene, especially in young individuals in whom an advanced arteriosclerosis may be excluded. To this type of kidney Naunyn has given the name "diabetes-kidney."

Diabetes with true nephritis occurs in a large proportion of the cases. It is usually engrafted upon an arteriosclerotic basis and the kidney is of the contracted type. According to Nothnagel the condition may be suspected when albumin is found in addition to sugar for a protracted period with few or no morphological elements. The urine is often of low specific gravity notwithstanding its sugar content. The diagnosis becomes assured if there is hypertrophy of the left side of the heart not due to valvular lesion.

It has often been observed that when albumin makes its appearance, the sugar excretion diminishes, or may even for a time entirely disappear. This, according to Naunyn, is in no way due to any reciprocal relation between the sugar metabolism and albumin. Any newly engrafted depleting condition that wears upon the health of the diabetic is likely to diminish the excretion of sugar, and such subsidence is to be viewed in the light of portending evil. Again, to quote Naunyn, "the occurrence of a true granular atrophy of the kidney, not on an arteriosclerotic basis is of great rarity in diabetes. In fact, the earliest symptoms of the nephritis often antedate those of the diabetes."

The relation of arteriosclerosis to diabetes has been scantily treated in the literature in comparison to the voluminous writings upon both diabetes and arteriosclerosis independently. That these two conditions occur together has long been known, and this combination has been variously estimated at from 40 to 80 per cent. of all diabetics. A discussion of the etiology of arteriosclerosis, itself a disputed question, need not be taken up here. It seems likely, however, that the diabetes itself does not weigh in the etiology of the arteriosclerosis, but, on the other hand, after once the disease is established, the diabetes seems to determine its character.

It seems more than probable that arteriosclerosis advances in a centripetal manner, beginning primarily in the smallest vessels of the various organs and tissues, and extending upward into the larger vascular trunks. It has been shown by Adler and others "that every arteriosclerotic vessel is associated with more or less complete fibrous induration of the territory it supplies." This insidious fibrosis probably begins in years long antedating the earliest advent of symptoms referable to arteriosclerosis, and probably therefore also antedating by many years in most instances even the earliest symptoms of aberrant sugar metabolism.

If now we consider the question of gangrene from this double viewpoint, regarding the subcutaneous tissues and the extremities as peripheral organs, we realize readily the interaction of the two morbific forces; on the one hand, a tissue reduced in vitality owing to a slowly advancing arteriocapillary thrombosis, and on the other hand a blood plasma of inferior quality. The relative value of these two factors varies in every case, but as regards the relative importance of the two factors in determining a gangrene, it seems to me the evidence is overwhelmingly in favor of arteriosclerosis.

We would be in error were we to consider the arteriosclerotic process as effecting only the periphery, however true this may be in some of the slowly gangrenous processes in diabetics, as exemplified in the second case of Davis's series, in which the process lasted about four years. The artery supplying the affected area shows arteriosclerosis in the vast majority of cases, according to Osler, and in many instances is thrombosed. Lloyd asserts that gangrene is usually due to thrombosis in the popliteal artery, with atheroma and calcification in a large percentage of cases.

Naunyn states that he has never failed to find obliteration of the pulse in the early stages of this complication. Von Noorden, in discussing whether to amputate the diseased portion in gangrene at once or to wait for demarcation, advises that we be guided by the same indications as for senile gangrene. This indirect answer teaches one but little. It has been said and frequently repeated that senile and diabetic gangrene are identical. This is certainly an error, although the difference is not marked. The protracted course of pure arteriosclerosis terminating in senile gangrene, gives the impression of a slow ischemic process. For months or years preceding the occurrence of gangrene there may be pain and claudication, and the process is usually unaccompanied by constitutional symptoms. The gangrene is of the dry variety and does not invite infection. Treatment is ineffectual and spontaneous amputation is the result.

Gangrene in the diabetic may be identical with that just described, if the arteriosclerosis is advanced and the diabetes mild. These are the cases, as will be seen later, in which recovery occurs with spontaneous amputation under dietetic treatment.

If the grade of diabetes is more severe, the arteriosclerosis may be less marked as a cause of gangrene, the arteriosclerotic process falling more in the background and the diabetic characters of the gangrene becoming more prominent. If prodromal pains were present they were probably ascribed to the diabetes. The dorsalis pedis pulse, if present, is much impeded. Gangrene is often preceded by a more or less diffuse mottling of the extremity. The gangrene less often involves the toes, but not infrequently occurs upon the plantar or dorsal surface of the feet.

When once gangrene is determined it seems to occur not so much by a slow ischemia, but suddenly, as though it occurred in a tissue partially devitalized and becoming suddenly completely so. The gangrene is usually of the moist character. It is accompanied often by excruciating pain. The process invites septic infection and constitutional symptoms. Ochsner, in a discussion of Halstead's paper, states that, "although pathologically there is no difference, there is a very decided and definite clinical difference between diabetic gangrene and arteriosclerotic gangrene. If in a diabetic one disposes of the diabetes, the tendency of the gangrene to spread subsides at once. On the other hand, if one does not dispose of the diabetes, there is a progression of the gangrene." He says, furthermore, that "by dietary treatment the gangrene can sometimes be made to subside, and the patient remains well."

The earlier inquiries concerning the blood pressure in diabetes were conflicting in their results. Potain, in 1902, and Teissier, in 1904, asserted that the blood pressure in diabetes was as high as, or higher than, in chronic nephritis. This was soon denied by Vaquez. Ott, in 1902, reported a wide variation in blood pressure in diabetes. One case occurring in an old man with albuminuria and glycosuria, in whom the systolic arterial tension was 225 mm., and a second case occurring in a young man of forty years, without albuminuria, but with a glycosuria of 6 per cent., in whom the systolic pressure was 105 mm. Since these early reports there have been many observations recorded. Janeway reports cases of both high and low blood pressure in diabetes. He has seen low pressure in severe cases of diabetes with marked emaciation and diacetic acid in the urine, and he has seen high blood pressure in mild forms of the disease in stout elderly people in whom chronic nephritis or arteriosclerosis existed. Elliott's series of twenty-five cases is very instructive; he believes, with Janeway, that the progressive emaciation and cardiac weakness, rather than the acid intoxication, cause the hypotension in the severe cases of diabetes.

The facts regarding arterial tension seem to be about as follows: The glycosuria seems to have little or no influence upon blood pressure. The acetone bodies seem to have no direct action upon the blood tension. The hypotension occurring in the

asthenic stages of diabetes is due in large measure to secondary cardiac weakness, and not directly to the diabetes. The hypertension occurring in diabetes is due practically to the arteriosclerosis and chronic nephritis.

Applying these facts to the question of diabetic gangrene, and with this conclusion my personal experience leads me to agree, a moderately high arterial tension is in the main to be accepted as more favorable than either excessively high or low tension.

In summing up the evidence in regard to these various factors in their relation to diabetic gangrene, we may deduce the following facts:

1. The hyperglycemia is not an important factor in the induction of the gangrene, but looms into importance after gangrene has been established in so far that it invites septic infection and encourages the occurrence of phlegmon.

2. Of the three acid bodies occurring in diabetes, acetone has a very low degree of toxicity, and probably does not contribute to the production of gangrene. Diacetic acid is always to be looked upon as a pathological ingredient of itself not very harmful and indicates that β-oxybutyric acid is being oxidized. β-oxybutyric acid, when present in the urine, is to be viewed as the special chemical agent fostering gangrene, which, however, is ineffectual in bringing about that result if acting alone in the absence of arteriocapillary sclerosis.

3. The quantitative ammonia excretion is the expression of measure of the amount of unburned β-oxybutyric acid. It is not an accurate standard of measurement, always registering too little. The excretion of one gram in twenty-four hours is to be looked upon as contraindicating operation except in great emergency.

4. Nephritis is to be looked upon as a complicating circumstance, having little direct bearing upon the occurrence or course of the gangrene. It is to be considered, however, as an element of added danger in regard to operation and anesthesia.

5. Arteriosclerosis is the most important single factor determining gangrene in diabetes. Arterial disease is not caused by the diabetes; many protracted cases of diabetes are unaccompanied by arterial degeneration. The course of arteriosclerosis in the presence of diabetes is somewhat different from that unattended by diabetes. This difference is probably due to the presence of β-oxybutyric acid in the blood in the latter instance. There is a difference between senile gangrene and diabetic gangrene. Senile gangrene is due to an endarterial ischemia, the gangrene of diabetes is due to the same cause plus a devitalizing factor acting probably chemically.

6. A knowledge of the tension is of value as a prognostic sign. Excessively high arterial tension is to be interpreted as an indication of advanced arterial change and probably interstitial nephritis. A low arterial tension indicates weakness from asthenia and secondary causes.

Armed now with these facts determinable in any given case of diabetes we may apply them in the following manner: First, prognostically, before the occurrence of gangrene even in the presence of a high glycosuria, a marked acidosis (which means diacetic acid alone or diacetic acid and β-oxybutyric acid), and advanced age, in the absence of arteriosclerosis and high blood pressure, we may look upon our patient as being not of the type to develop gangrene. And again, from the prognostic standpoint, a patient not past forty years, with a low percentage of sugar, with no acidosis, but with an interstitial nephritis and a marked arteriosclerosis, we may look upon as belonging to the type of those who may acquire gangrene.

The advisability of operating must be estimated for each case independently. In regard to this question the amount of suger excretion may be ignored, but every attempt should be made to reduce it. A great and sudden falling off of the amount of sugar excretion is a warning of danger. A high excretion of sugar does not necessarily contraindicate operation.

The value of a knowledge of the acetone bodies in its application to the question of amputation is limited. In the absence of this reaction, or when it is not marked, even though other symptoms of diabetes are severe, there is a strong likelihood that with a fair trial of medicinal and dietetic measures, the gangrene will not advance, and in time spontaneous amputation will occur. The extreme view adopted by Klemperer is significant, and suggests a conservative attitude regarding operation, to which views my experience would also tend to lead. There is usually no serious loss of time unless phlegmon be present in this type of case, and astonishing results may occur with the employment of rational conservatism. Even when the acidosis is severe it is wise to allot a reasonable time to a faithful trial of nonoperative methods; these failing, however, amputation becomes then our sole recourse.

ANESTHESIA BY MEANS OF CHLOROFORM AND ETHER.

By EDWARD PENDLETON, M.D.,
RICHMOND, VIRGINIA.

This subject is of great importance and interest, not only to the anesthetist, but to the general practitioner as well. It is my desire to present a few facts that will be helpful in the administration of chloroform and ether. If possible, the patient should enter a hospital at least six days prior to the operation. He should be given plenty of good, nutritious food, easily digested, and should drink plenty of water. An examination of the urine should be made at least twice, and if any trace of albumin is found, ether is contraindicated. The heart should be carefully examined, and if any lesion is found, under no circumstances shall chloroform be given. If any disease of the lungs is present ether is contraindicated.

When the patient first enters the hospital a half-dozen broken doses of calomel with soda should be given, followed the next morning before breakfast by a saline, which will wash away all the bile that has been thrown out during the night. The patient should be encouraged to drink a glass of water every half hour, for two or three days; in this way the kidneys will get a good flushing. No solid food should be taken into the stomach six hours previous to the administration of an anesthetic. The night before the operation the patient should have a mild saline cathartic, and on the following morning receive an enema of warm soap suds 1 quart, glycerin 1 ounce, and turpentine 1 dram. Before one takes an anesthetic the surgeon should always see that the stomach, bowels, and bladder are empty.

At times it is very hard to decide just which anesthetic is best to give, but each case should be a law unto itself. Let the anesthetizer study his patient carefully; be careful in getting the history, the habits of the patient, nature of the operation, and its probable duration. Care should be taken in examining the heart, lungs, and kidneys. If the patient is an alcoholic, or is suffering from aneurism, kidney disease of any type, or an atheromatous condition of any of the arteries, it is best to give chloroform. The danger of chloroform is in the early stage, and death from this agent is due to respiratory paralysis; in some cases it is really safer than ether on account of the after-effects produced. Pneumonia, following the administration of an anesthetic, especially ether, is not due so much to the irritating fumes of the ether, but to the exposure; hence the patient's chest and arms should be well covered; and when being moved through hallways he should be covered with a blanket.

When giving an anesthetic there are two dangerous symptoms to watch for, and when either is discovered the anesthetic should be discontinued or suspended. These symptoms are: Sudden dilatation of the pupil and hiccough. The stomach should be washed out with plain warm water, especially before an abdominal operation, and it is desired to keep the abdominal viscera as quiet as possible, for by so doing the patient is less likely to vomit. A hypodermic of sulphate of atropine 1/100 grain, given thirty minutes previous to an anesthetic, will diminish the amount of mucus in the mouth and pharynx, and will retard the tendency to vomit. It also acts as a respiratory stimulant. Before an anesthetic is given the mouth should be examined for artificial teeth and foreign bodies, such as chewing gum or tobacco.

The patient should lie recumbent, and, if possible and convenient, in the Trendelenburg position. It should be impressed upon the patient's mind that there is practically no danger. Everything should be loose around the neck, chest, and abdomen. The face should be anointed with vaselin, especially around the eyes, nose, and mouth.

Ether given by the drop method is more satisfactory than the use of the closed cone. Nephritis is more likely to occur after ether than chloroform. Often it is due to the shock following the operation. When ether is given slowly there is no respiratory spasm or coughing.

Chloroform is best given by the drop method, using the Allis inhaler. The Gwathmey apparatus is also considered good for chloroform.

"W. Hunter, in discussing chloroform in the *Lancet*, April 4, 1908, says that vomiting occurring after the administration of chloroform is not of nervous origin, but essentially toxemic, due to the profound depression of liver function, with consequent diminution of its antitoxic function during the period of its administration of the chloroform."

No anesthetic should be administered without having the following articles on hand, on a table near the anesthetizer: One hypodermic syringe loaded with nitroglycerin, 1/100 grain; one loaded with strychnine sulph., 1/30 grain, and atrophine sulphate, 1/150 grain; one loaded with ether or brandy; ½ dozen pearls nitrite amyl; an ounce of vaselin for the patient's face; eight ounces of ether; eight ounces of chloroform; one mouth gag; one pus basin; two long sponge forceps and gauze for mopping the mouth and pharynx; one tongue forceps; one large needle threaded with heavy silk; three towels. Before giving an anesthetic it is well to wrap the patient's head in a sterile towel. Especially is this necessary if the operation is to be about the face or neck, as it prevents the hair from getting soiled.

Commence by giving only a few drops at first of ether or chloroform; hold the inhaler about two inches from the patient's face, and tell him to breathe naturally. Do not tell the patient to take deep breaths, for this will only cause coughing and struggling. Every half-minute add five or six drops, telling the patient to go to sleep. The inhaler can be held in the left hand, and with the fingers of the right hand resting and pressing forward on the angle of the jaw. Keep the index finger constantly on the temporal artery. Do not watch the chest to see if the patient is breathing, but put the ear over the inhaler and you can tell better. Care should be taken in putting the fingers on the conjunctiva to see if the reflex is lost, for serious inflammation may result from too frequent and rough handling of the conjunctiva. When you lift up the patient's arm, and it falls limp, it is a pretty sure sign that the patient is ready. Some surgeons make the skin incision before the patient is thoroughly anesthetized. This causes the patient to move and breathe deeper, thereby getting under the influence of the anesthetic sooner. It is not necessary to carry the patient to the third stage of anesthesia, but only so much shall be given as to keep him from suffering or struggling. The anesthetist should go with the patient to the ward after the operation is over, constantly pressing on the angle of the jaw, so that the tongue may not fall over the glottis. The patient should be left in the hands of a competent nurse, who should stay by the bedside until the patient is thoroughly conscious.
